VIOLETTE further examined several varieties of charcoal, all of which were prepared at 572° by both the foregoing methods; they inflamed between 680° and 716°, but in no case did they take fire at a lower heat than 680°. He observed that the charcoals from light woods generally ignited a little before the product from the harder kinds, with the exception of one, which is remarkable, namely, the charred product of the fungoid excrescence of the willow tree (*agaric de saule*). The latter was observed to take fire in one instance at a temperature so low as 572°, and in every experiment at 608°. Hence it is the most inflammable of all species of charcoal; and, as the above-named investigator remarks, had it been prepared at 500° instead of at 572°, doubtless its spontaneous combustion would take place at a lower temperature than even that given. It may well be inquired to what may this peculiarity be attributed? and, doubtless, as VIOLETTE suggests, the organic molecular state of the substance might exercise some influence whereby its rapid ignition is induced.

To sum up these results, it will be seen—

1. That the most inflammable of all wood charcoals (*agaric de saule*) takes place at 572°.
2. That the charcoals from different kinds of wood, when prepared at a constant heat of 572°, spontaneously ignite between 698° and 734°, according to the nature of the wood producing them; but that the product from the lighter burns quicker than that of the denser woods.
3. That charcoals from the same wood, only prepared at increasing temperatures, spontaneously undergo combustion at very unequal degrees of heat, as shown in the table, page 50, *ante*.

After attentively considering these results, very little doubt will remain as to the best means of carbonizing the wood. To a certainty the temperature of the charcoal, as prepared by most of the methods indicated under the charring of wood, vol. ii., *et seq.*, and also under ACETIC ACID, exceeds the limits laid down by

VIOLETTE; and, therefore, it follows that the combustion of a powder made by such materials will require a greater amount of caloric to induce its decomposition than if the charring heat was less. Where the process by superheated steam or gases is not adopted, evidently the choice should be decided in favor of that method which furnishes the charcoal at the lowest degree of heat. There are three methods in ordinary use by which the charcoal for the powder manufacturer is prepared, namely, the pit, the furnace, and the closed retort. When pits are selected, they are made smaller than those described in the foregoing articles, and the walls and sides, together with the apertures for the introduction of air, are constructed with more care; the wood is also arranged in them with greater caution, and the combustion watched so that, during the operation, the whole may be completely acted upon, and no half-burned material left. In the general particulars, however, no difference exists between the methods already alluded to and this, so that it will be needless to repeat the description. The product amounts to sixteen or seventeen per cent. of the wood. If the carbonization is effected in furnaces, the quantity of the product will not be so large; besides the consumption of fuel will be greater than in the preceding case. In England, however, the charcoal obtained by the distillatory process in closed retorts is always preferred, although a considerable expenditure of fuel is occasioned in heating the vessels. The apparatus described at vol. i., page 17, is the same as used in this operation. When the process of carbonization is coming to a close, the pipe connecting the cylinder with the pyroligneous-acid receiver must be closed, and very free egress must be allowed for the volatile matter; otherwise the charcoal is liable to injury by the deposition of a fuliginous varnish, and even by its reception of, and saturation with, condensable matter.

TOMLINSON, who writes the excellent article GUNPOWDER in the *Encyclopædia Britannica*, is inclined to consider this preference for distilled charcoal a mistake of the *causa pro non causa*. Pit charcoal, being made in coppice woods, is always the produce of oak; and it is probable that this wood, if charred in close vessels, would be even worse than it is now. There is more danger of overheating in the retort than in the pit, while the wood is not better burned; and hence, by a careless management of the process, even the charcoal of willow and alder may be rendered as bad as that of oak. Considering these various circumstances, charcoal requires to be submitted to three tests. It ought to act as little as possible mechanically, even on copper; no salts should be extracted from it by treating it with boiling distilled water; and it ought to give out no smoke when heated. The latter test is indicative of its being thoroughly burned.

The selected wood, whatever its variety, should always be cut when in sap, and never when dead. Wood of five or six years' growth is better suited for the manufacture of the charcoal than older kinds; for, generally, the latter contains more mineral matters, and, consequently, less carbon than the former; and the most convenient size is branches from three-quarters to an inch in diameter.

The charcoal, says Dr. URE, is considered by the scientific manufacturers to be the ingredient most influential, by its fluctuating qualities, upon the composition of gunpowder; and, therefore, it ought always to be prepared under vigilant and skilful superintendence. If it has been kept for some time, or quenched at first with water, it is unsuitable for the purpose. Charcoal extinguished in a close vessel by exclusion of air, and afterwards by exposure to the atmosphere, absorbs only from three to four per cent. of moisture, while red-hot charcoal quenched with water may lose, by drying, twenty-nine per cent. When the latter sort is used for gunpowder, a deduction of weight must be made for the water present. Charcoal, however, which has remained long impregnated with moisture, constitutes a most detrimental ingredient of gunpowder.

Before entering upon the description of the process for compounding the substances which constitute gunpowder, it may be well to give a few additional facts relative to the circumstances which affect the mutual decomposition of those bodies as they exist in this article, and render the phenomena of its explosion more easy of comprehension. Already some experiments of PROUST have been adduced, which elicit comparative data of the explosiveness of certain varieties of charcoal when mixed intimately with saltpetre; but they do not afford any real knowledge as to the degree of heat required to bring about such a metamorphosis, although they indicate that some kinds of charcoal form more inflammable mixtures with nitrate of potassa than others. The investigation of VIOLETTE upon the temperature at which charcoal decomposes this agent, is much more definite, and consequently interesting. He found that the degree of caloric which occasions the combustion of charcoal in the air, is much lower than what is necessary to cause the carbonaceous matter to decompose the oxidising agent which is incorporated with it in the powder. To determine this, he proceeded thus:—In a small porcelain crucible, heated by a carcel-lamp, which allowed the temperature to be easily regulated, nitrate of potassa was melted and maintained at 680° , being the degree at which the charcoals burned in the air. Into this bath a small cylinder of charcoal appended to a platinum wire, or glass rod, is plunged, so that it is all submerged; although numerous bubbles of gas were disengaged, yet the carbonaceous mass did not take fire at this temperature. By raising the heat gradually to 716° , and, trying the experiment at this stage, the effect was still negative, but ultimately it deflagrated after the bath had been raised to a higher degree of heat. The fusion of lead and zinc showed the thermometric effect to be above 680° ; but it being incapable of melting antimony, it was evident that the heat had not reached 819° , the fusing point of the latter metal. It may be concluded, therefore, that all charcoals prepared between 500° and under to 819° decompose nitrate of potassa at 752° , but that such as are obtained between 1832° and 2732° are not affected at the preceding, nor at much higher heat, since they do not even burn upon the surface of the bath.

The same chemist determined the degree of heat at which sulphur decomposes nitrate of potassa in an

equally ingenious way. He found that when sulphur was thrown upon the surface of the bath of fused salt, raised to the temperature of 680° , it floated about, melted, and inflamed; the combination, however, was with the oxygen of the air, and none of the saltpetre had been acted upon. A similar result was arrived at when the bath was at 752° , or even a few degrees higher; but when it had attained 819° , the fusing point of antimony, deflagration occurred by the decomposition of the potassa salt, and the evolution of a brilliant white light and a considerable quantity of gases. In the latter experiments it was necessary that the sulphur, like the charcoal in the last-mentioned examination, should be immersed in the fluid bath. To do this, VIOLETTE had a platinum crucible about the size of a pea constructed, and to this he appended a platinum wire, which might serve as a holder to it when immersed, mouth-under, in the bath. When 0.1 grain of sulphur was melted in this tiny vessel, and plunged into the bath in the manner shown in the annexed diagram, the effect was observed with considerable accuracy. Until the heat had reached the decomposing degree, the sulphur was observed to ascend in bubbles of colorless vapor through the transparent bath, and burst into a beautiful blue flame. As soon as the inflammation of the sulphur commenced within the fused saltpetre, the white light traversed the whole mass with the effect already detailed.

Fig. 247.

An observation of VIOLETTE's is worthy of notice here. During his examinations of the combustion of sulphur in nitrate of potassa, he tried at what temperature this element burns in the air, but found that the limits which are stated with reference to it in chemical treatises differed, both from one another as well as from his results. DUMAS gives the combustion of sulphur in air as taking place at 302° ; DALTON states that the heat is 500° , and THOMSON, 561° ; but VIOLETTE affirms the melting point to be exactly 480° . His experiments were performed on the surface of a bath of tin; contact of the sulphur and metal being avoided by placing it upon a thin pellicle of glass, and floating the latter upon the hot metal.

It was also observed that by sprinkling a little sulphur upon charcoal thrown upon the surface of the heated bath, ignition took place under the degree at which the most combustible charcoal kindles, *per se*. This occurs on account of the heat developed by the combustion of the sulphur at 480° , and which brings the charcoal to the state of redness, and consequently at which, when air is supplied, it rapidly inflames.

PROPORTIONS OF THE INGREDIENTS.—The progress of improvement in determining the proportions of the constituents of gunpowder, has been very gradual. In this country, a long period elapsed before the present state of perfection was attained; but this cannot well be wondered at, when one takes into consideration the ignorance which existed even up to the commencement of the present century, not only with regard to the theoretical laws of science, but also in respect of the properties of bodies purely chemical.

Such compounds as saltpetre, sulphur, and charcoal

in equal proportions were scarcely fit for squibs, much less for the purpose of projecting shot. Again, one finds such mixtures as saltpetre twelve parts, with three each of charcoal and sulphur; twenty-seven of nitrate of potassa to three of each of the other ingredients; saltpetre forty-eight, sulphur seven, and charcoal three parts; with many others which now-a-days appear equally ridiculous. At no very distant period, the French compositions were, saltpetre fifty, sulphur sixteen, charcoal thirty-four parts; saltpetre sixty-seven, sulphur thirteen, charcoal twenty; and again, saltpetre eighty-four, sulphur eight, and charcoal eight parts.

BAPTISTA PORTA was one of the first who endeavored to ascertain the best relative quantities of the constituents, and his proportions, obtained in the year 1515, approached very nearly those now employed in France. The deductions of GUYTON MORVEAU, BEAUMÉ, CHAPTAL, PROUST, and RIFFAULT, are represented below:—

DUMAS gives the proportions, saltpetre 75, sulphur 12·5, and charcoal 12·5, as the most ancient known, and states, that however these proportions have been deviated from, either from pressing circumstances of time or place, the powder manufacturer had in the end to fall back upon the above mixture as offering the best composition. This seems to be the case, since the researches of the several original chemists who have taken up the question give mixtures closely approximating to those numbers, as may be seen from the annexed table of the mixtures recommended by them.

	Saltpetre.	Sulphur.	Charcoal.
Guyton Morveau,	76	9	15
" "	77	7	17
" "	80	5	15
Beaumé,	80	5	15
Chaptal,	77	9	14
Proust,	78	9	13

To these may be added the following:—

	Saltpetre.	Sulphur.	Charcoal.
Powder of Bâle,	75·0	10	14
" Grenelle,	76·0	12	12
" Riffault,	77·5	7·5	15
" Bouchet,	77·0	9·5	13·5

Of the latter class, that of Bâle is accounted the best for military and general warlike purposes; but, notwithstanding the superiority it possesses when recently prepared, if the compound has to be retained for a long time in magazines or to endure long transport, it does not answer so well as the old proportions above referred to. Theoretically considered, this is, granting that all the materials possessed absolute purity, the best composition; for if the nature of decomposition of powder be attended to, and the products of the combustion examined, it will appear that only carbonic acid, nitrogen, and an alkaline sulphide are produced. Hence it may be reasonably inferred that the chemical symbol corresponding with this decomposition, admitting of no loss, would be,—

—that is, one equivalent of saltpetre, three of charcoal,

and one of sulphur, by being made into a powder, affords one equivalent of sulphide of potassium, three of carbonic acid, and one of nitrogen. Calculating from these data the percentage quantity of each to be taken, the annexed results are obtained:—

	Theoretically.	Practically
1 Eq. of nitrate of potassa,	101	74·81 = 75·0
1 Eq. of sulphur,	16	11·85 = 12·5
3 Eqs. of carbon,	18	13·34 = 12·5
	135	100·00 100·00

The difference between these numbers is so minute as to be worth noticing, even were nothing else to be taken into account; but as shown by the analysis of several charcoals, as given under FUEL, there is always more or less hydrogen present, which concurs to make the combination more complete, and in accordance with theoretical results. Another instance of the accuracy of the quantities taken for the preparation of another quality of powder, is the variety generally used for mining and blasting purposes. The proportions taken for this are:—

Saltpetre, 65; sulphur, 20; charcoal, 15;

Numbers which closely correspond with the formula,—

Sporting powder is another of these compositions which may be reduced to the simplicity and certainty of a chemical formula. The usual quantities of the materials taken in this case are:—

Saltpetre, 78; sulphur, 10; charcoal, 12;

Numbers which may be expressed by equation, although this is not so simple as the preceding, owing to there being a slight excess of oxygen over and above what the charcoal combines with, and the amount of sulphur used being incapable of retaining all the potassium in the state of sulphide. This will be seen from the formula,—

That is, eight equivalents of saltpetre, six of sulphur, and twenty-three of carbon, afford five equivalents of sulphide of potassium, two of carbonate of potassa, and twenty-one of carbonic acid and eight of nitrogen. The truth of the formula is proved in a very striking manner by the following calculation:—

	Centesimally calculated formula.	Given mixture.
8 Eqs. of nitrate of potassa, ..	808	77·54 .. 78
6 Eqs. of sulphur,	96	9·21 .. 10
23 Eqs. of charcoal—carbon, ..	138	13·25 .. 12
	1042	100·00 100

The analogy in both the foregoing instances is suffi-

cient to show that the powder-maker has in compounding his mixtures an unfailing guide, by following which he cannot get far wrong. A little difference is occasioned in the foregoing, in the quantity of the calculated charcoal especially; but the explanation of the presence of hydrogen, which takes up such a large quantity of oxygen from the nitrate of potassa during the explosion of the powder, accounts for this. Indeed, were it not for this excess of hydrogen which makes up for the assumed amount of carbon in the charcoal, it would be difficult to reduce the quantities of real matter in the substances within the expression of a simple formula. Analyses show that the quantity of carbon in the charcoals which are usually incorporated, varies from sixty-eight to ninety per cent., and it is evident that when numerical quantities of the ingredients, such as ex-

pressed above for the manufacture of the powder, are strictly adhered to, serious differences occur in the quality of the article, according as the charcoal is more or less rich in carbon. To adhere, therefore, to the strict proportions indicated by the numbers laid down, and which assume that the materials are pure, it becomes absolutely necessary to determine the amount of carbon in the charcoal, and regulate the quantity according to such an estimation; otherwise it is not at all surprising that two powders prepared exactly according to any given recipe, but with different materials of unknown qualities, should have very unequal effect when exploded.

The following table shows the proportion of the ingredients used by the powder-makers of different nations:—

Countries.	Artillery Powder.			Musket Powder.			Sporting Powder.		
	Saltpetre.	Sulphur.	Charcoal.	Saltpetre.	Sulphur.	Charcoal.	Saltpetre.	Sulphur.	Charcoal.

Several other proportions are in use in the countries specified above, which, to some extent, vary from those given. It is reasonable to suppose that in choosing the foregoing numbers, the manufacturers of the several countries mentioned have conscientiously selected the numbers given as affording the best results; still, as there seems to be no tabulation of the composition of the materials, more especially of the charcoal, the Editor believes that a considerable amount of empiricism must be connected with it; at all events, the variation in the proportions must be attributed to the inequalities in composition of the varieties used: for, had each sought the most appropriate mixture, and employed charcoal of a known per-centage of carbon, doubtless, instead of the many variations, one invariable proportion would be adhered to by all, and a close analogy in the explosive force of the powder could be calculated upon. The species of powder which is used for mining and similar purposes vary in composition from the kinds used for the military and for sporting; it has a much larger proportion of charcoal than the latter, and consequently it is less expensive. From the example given in the preceding of the parts of such powder centesi-

mally, and the exposition of its decomposition by a rational formula, this is shown to be the case: besides, the products of the explosion contain, with carbonic acid, a large volume of carbonic oxide. As will be shown further on, the volume of gases which such a powder affords is larger than what results from the shooting powder; but still the propulsive effect is less than with the latter.

With reference to the study required to insure the production of the best possible compound, and to find a general recipe, VIOLETTE submits a suggestion to which the Editor subscribes, as it would contribute more than anything else to register the quality of the various powders and excite inquiry; namely, that a register of the propelling powder should be kept annually, and such submitted to a competent party for consideration. As to the indications in the targets, however, they are liable to be affected by the nature of the piece; and, in fact, the powder itself, when made from precisely the same ingredients by two neighbouring establishments, varies in some measure, in consequence of the dissimilar manipulations.

To ascertain how far the powders prepared from

variable quantities of materials of the same centesimal composition differ in their ballistic effect, VIOLETTE prepared a number of samples of fowling powder, each weighing about twenty kilogrammes, forty-four pounds, and submitted them to the test. The following are the results :—

No.	Per-centage composition of materials.			Amount of carbon in one hundred parts of charcoal.	Speed of the ball by the ballistic pendulum.
	Saltpetre.	Sulphur.	Charcoal.		
1.	78	10	12	68	357
2.	72	9	19	68	350
3.	72	10	18	68	355
4.	71	10	19	68	361
5.	71	11	18	68	363
6.	71	9	20	68	370
7.	71	11	18	85	337

In this table No. 1 is the regular proportion, and the speed of the ball with such, supposing all the powder to be consumed, would be, according to the usual rule, three hundred and fifty metres. It is surprising to observe that No. 6 in the above collection, in which the saltpetre is diminished by eight parts, and the sulphur by one, and the charcoal increased by eight, is a superior powder to No. 1. No. 5 also constitutes a very good powder, but its quality would be considerably deteriorated by using, instead of the charcoal containing only sixty-eight per cent. of carbon, one yielding eighty-five per cent., as shown in the last. This forms a striking example of the way in which an inequality in the per-centage of carbon in the powder affects it.

The chief qualities which a good gunpowder ought to possess, are ready inflammability, complete decomposition of its constituents, the production of the largest possible volume of elastic gases, and finally, that of affording only the smallest possible amount of residue, and even that should be of such a nature as not to injure the gun.

Inflammability of Powder.—From what has been stated in the preceding pages relative to the degrees of heat required to decompose the constituents of powder, a good inference may be drawn as to the degree of heat at which powder will take fire.

However, if a small quantity of powder be slowly heated, and the temperature be gradually raised, it will be observed that the sulphur, which is the most inflammable constituent, will begin to burn with a blueish flame at 482°, or thereabouts; and the heat developed in this partial combustion brings the other constituents into that state at which the nitrate of potassa is decomposed by the charcoal, whilst the remainder of the sulphur adds to the effect by combining with the metal of the oxidising agent, thus—

To ascertain whether the powders, as usually manufactured, actually do ignite at the burning point of sulphur, VIOLETTE made some examinations by placing portions of the powder to be tested on the surface of a bath of tin, in which the bulb of a thermometer was immersed, the whole being heated by a small carcel-lamp: the following results were obtained—

No.	Species of Powder.	Temperature which produced deflagration.	
		Powder in angular grains.	Pulverized powder.
1.	Blasting powder,.....	518°	509°
2.	War ".....	528.5	510.5
3.	Sporting " fine,.....	536	514.8
4.	do. " extra-fine,....	608	518.0

Of these No. 1 was made with black charcoal, and No. 4 with brown or torrefied charcoal, the inflammability of which takes place at a much lower degree of heat than the first; still it is a matter of some surprise to find that the former, in the shape of powder, burns at a lower heat, excepting the variation in the quantity of sulphur present in them may influence the deflagration. This element is present in the four samples in the following ratio, namely, 20, 12.5, 10, and 9 per cent.; the most combustible of the powders having the largest amount of sulphur, which, of all the elements, is the most ready to enter into ignition. It may likewise be remarked that the size of the grain influences, in some measure, the temperature at which the powder burns.

Balistic or Propulsive Effect of Gunpowder.—The force with which a ball is projected, or a rock fractured, is, as may be easily understood, in proportion to the volume of gases which is produced when gunpowder or any other modification of this article is deflagrated. In case of gunpowder, these gases are principally carbonic acid and nitrogen; and where mining powder is operated upon, carbonic acid is likewise a product. But besides these it is found that small quantities of many other products are invariably formed, among which may be mentioned carbonic oxide, sulphurous acid, sulphide of hydrogen, bisulphide of carbon, carbonate of potassa, cyanide, and sulphocyanide of potassium and aqueous vapor. The most important products of a careful and complete combustion, on a small scale, of powder of the above composition, have, however, been found to correspond pretty closely to the above theoretical expression.

The gases disengaged in the combustion of this powder, would comprise, at 32°, a volume three hundred and twenty-nine times as great as that occupied by the powder. The force exerted by the evolution of these gases is, however, mainly dependent upon their enormous expansion at the instant of the explosion, by the heat evolved in the action; for it is calculated that one volume of powder of the above composition yields, at the moment of ignition, at least two thousand times its volume of gas.

If gunpowder contain more carbon in proportion to the nitrate of potassa than the quantity above stated, a proportionate amount of carbonic oxide is produced in its explosion; thus if six instead of three equivalents of carbon be employed to one equivalent of saltpetre, the whole of the oxygen contained in the latter would theoretically be eliminated as carbonic oxide on the decomposition of the powder, as the following equation shows :—

Now, since the space occupied by equal equivalents of carbonic oxide and carbonic acid is the same, it is evident that a much larger volume of gas would be evolved—calculated for a temperature of 32° , and ordinary barometric pressure—from the gunpowder which contained the larger amount of charcoal. But it must be borne in mind that the amount of heat disengaged in the production of carbonic oxide is far less than that generated when carbonic acid is produced, and that consequently the powder which contains the minimum quantity of charcoal will yield, *at the instant of explosion*, by far the greatest bulk of gas. That this expansion of the gas by heat is of the utmost importance, is very evident from what has been already stated. The fact that the temperature evolved by the combustion of gunpowder, estimated at 2192° , has been found to be sufficiently intense to fuse gold, silver, and other metals, and that the expansion of gases increases greatly with an augmentation of temperature—two hundred volumes of gas raised to 2428° occupying the same bulk as three hundred volumes, which are only heated to 1466.6° —render the value of a slight elevation of temperature at the moment of explosion still more apparent.

As it is difficult, nay impossible, under ordinary circumstances, to gain a knowledge of the quality of powder by any method involving the necessity of measuring the gases and caloric evolved, a more direct course of experiments is resorted to. This method was founded by PROUST partly upon the duration of the combustion, coupled with the volume of gases which were eliminated. The methods of operations employed were the same as those already described with regard to the estimation of the time required to deflagrate charcoal and nitre, *et cetera*. The following were his results:—

No.	Saltpetre.	Sulphur.	Charcoal.	Time of combustion in seconds.	Products in gas in cubic inches.
1.	60	10	15	6	91
2.	60	10	12	6	91
3.	60	10	10	6	91
4.	60	10	$8\frac{1}{2}$	7	88

It is presumed that these determinations, however, leave much to be required, not only in the accuracy of the determinations, but with respect to practical application.

TOMLINSON adopted another method, which, on the whole, is more applicable to practice—namely, the determination of the altitude of rockets, and which he describes as being less liable to disturbances from collateral causes than any practice with pieces of ordnance. The rockets were of compound dimensions, and were all made with the same proportions and driven with the same hand, so as to insure all possible uniformity; the only variation being in the nature of the charcoal. The vertical elevations were taken by two quadrants at the same time, and all the flights that deviated from the perpendicular were rejected. The mean vertical ascent made with a great number of these, in which the charcoal was from the willow, alder, and dogwood, was four hundred and eighty yards; but between these three charcoals the difference was so great as to give various results, which may be represented by the following numbers:—

Dogwood charcoal,.....	515, 550, 525
Willow “	470, 480, 490
Alder “	455, 460, 470

To the methods in use, and recognized by the military and powder manufacturers generally, reference will be made further on.

Upon comparing the composition of the powders prepared in different countries for fire-arms, they will be found to agree more or less closely with the cen-

Fig. 248

tesimal composition as above expressed. It must be remembered, however, that the proportions have been arrived at by experience, in most cases long before any

theory concerning the chemical composition or action of powder was advanced. In some cases the deviations from the theoretical numbers may be readily ex-

plained. Thus in the manufacture of the Waltham Abbey powder, a slight excess of charcoal is always employed in order to allow for the small quantity of inorganic matter always associated with carbon in that form; while the proportion of sulphur is reduced as much as is compatible with the production of a strong powder, in consequence of the injurious action of that substance, and even of sulphides in the presence of moisture, upon metal.—*Abel and Bloxam.*

MANUFACTURE.—The merely mechanical part of the manufacture of gunpowder is essentially the same in principle, and differs only to an immaterial extent in detail, whether in the various gunpowder mills in Great Britain, or in those of her continental neighbors. The Editor will trace the method of manufacturing gunpowder as it is employed at the Government Mills, Waltham Abbey:—

In the first place, it may be stated that water is the motive power in most gunpowder mills; the necessity of the presence of fire when steam is made use of is attended with so much danger, that this agent has not yet been introduced for the purpose.

The gunpowder mill is represented in Fig. 248, where A is the water-wheel; BB, two vertical bevel wheels fixed upon the axis of the great wheel, and working into CC, which turn the shafts, DD; EE are two horizontal spur-wheels, fixed to the upper part of DD, and driving the large wheels, FF. To the shafts of these latter are fixed the runners, GG, which traverse the bed-stone, HH; II are the curbs surrounding the bed-stone to prevent the powder from falling off; K is the scraper.—*Ure.*

The materials, having been pulverized in the mill, are apportioned out, the following being the proportions at Waltham Abbey:—

	Pounds.	Ounces.	Drachms.	
Saltpetre,	31	8	0	0
Charcoal,	6	4	13	
Sulphur,	4	3	3	
	42	0	0	

This quantity of the ingredients, termed a *charge*, is placed in the mixing apparatus, which consists of a wooden cylinder traversed in its centre by an octagonal shaft provided with several fan-like arms. Both the shaft and cylinder are kept in motion, but in different directions. This latter arrangement so facilitates the commingling, that the homogeneous powder is ready for removal and further manipulation in from five to ten minutes, when it is transferred to bags which are pressed, and the mouths of which are firmly secured, in order to prevent the disunion or separation of the ingredients in the order of their density, during the transport to the incorporating mill. It is evident that if the charges were too lightly packed, the ingredients would be liable to be separated in a greater or less degree, the saltpetre finding its way to the bottom, while the sulphur and charcoal would form layers above; the latter, from its light, pulverulent state escaping, in the form of dust, between the fibres of the cloth of which the bag is formed.

The next process is the *incorporation*. The mixture is spread out upon the bed of the mill, distilled water is added to insure the intimate cohesion of the par-

ticles—the amount of water required varying much according to the temperature and other atmospheric conditions, as also in proportion to the degree of comminution of the constituents—and the whole is again submitted to the action of the mill, to insure the uniform pressure and bruising of the rollers; but in this case the motion is less rapid than during the grinding of the ingredients. A great degree of caution must be exercised to prevent the intervention of any hard or silicious matters. The requisite amount of moisture must be maintained during the operation, and for this purpose water is slowly added at suitable intervals, till the incorporation is complete, which is generally the case at the expiration of from three to four hours.

The homogeneous compound has now the properties of gunpowder; it indurates in a very short period, forming hard cakes, which should possess a dark greyish-black hue, and free from specks of any kind; it is now termed *mill-cake*. When this has lost much of its moisture, but before it becomes completely dry, it is passed between corrugated or channeled cylinders, termed the *breaking-down mill*, and is then submitted, between copper plates, placed in strong boxes, to hydraulic pressure of about one hundred and twenty tons per square foot, after which it is known as *press-cake*; it is now greatly altered in appearance, and apparently resembles slate, being in dense blackish cakes, about half an inch in thickness. This powerful pressure is productive of several advantages:—

1. The powder has a greatly augmented density, and a given quantity of it will evolve, on combustion, a far larger volume of gas, than an equal bulk of powder which has only received the pressure of the incorporating mill.

2. From the increased hardness of the powder, it better resists atmospheric action; and besides this, it is not so liable to loss from *dusting*, caused by friction, during its transport.

The powder has now to be granulated. The machine employed for this purpose at Waltham Abbey consists of a pair of metal cylinders, provided with large teeth, upon which, while in revolution, the press-cake is allowed to fall in fragments; by this means it is reduced to grains of various sizes. As these pass from the cylinders or rollers, they are submitted successively to the action of three sieves of graduated fineness, placed one over the other, and jolting or working continually backward and forward. The powder retained by the first sieve is subjected to the action of a second pair of rollers with finer teeth, whence it again passes to, and is sifted by, the upper screen. The portions still too coarse to pass through, are reduced by a third still finer set of rollers. The powder manufactured at Waltham Abbey is distinguished as L. G., or *large-grain*, F. G., or *fine-grain*, and *meal-powder*, or dust. The first variety is retained by the second sieve; the lowest sieve reserves the fine grain; the dust, or meal-powder, collects beneath. Each kind is collected, as it falls from the screen, in boxes running on wheels and rails.

Various other contrivances belong to this effective machine to obviate the necessity for the attendance of

workmen, and, consequently, to prevent their injury should any accident occur.

The granulated powder is next freed from dust by running it through *reels*, similar to the bolter employed in dressing flour—encased in boxes, and covered with canvas or with silk, of about fifty-six meshes to the inch, according as large or fine-grain powder is introduced.

The finest powder is now *glazed* by subjecting it, in a slightly moist state, to rotary motion in barrels or drums, similar to the mixing machine already noticed. The velocity of rotation must be just sufficient to cause the grains only to roll over each other slowly, and thus become polished by attrition. Blasting-powder is occasionally glazed with graphite.

The gunpowder is finally dried, which is now generally done by means of steam-heat; sometimes it is effected by transmitting a current of air, previously heated in another chamber to from 130° to 150°, over the powder placed on canvas shelves.

On the Continent, the powder is chiefly granulated in drum-sieves, generally made of perforated parchment skins or of copper, fitting into each other, and fixed in a frame to which rotary motion is communicated by proper machinery. On the uppermost of these is placed a circular piece of heavy wood, as *lignumvitæ*, sometimes loaded with lead, which traversing the surface of the sieve, gradually reduces the fragments of the powder, until they are sufficiently fine to pass through the perforations or meshes.

PROPERTIES.—Good powder, according to ABEL and BLOXAM, should be perfectly uniform in texture; light specks or glittering points indicate an incomplete mixture. The grains should be sufficiently hard not to be easily crushed between the fingers, and not to soil these or a piece of paper by mere contact. Gunpowder should burn rapidly, leaving only a *very slight* residue. If inflamed upon white paper, it should blacken it but slightly, and should on no account set fire to it. Powder is inflamed by any burning substance, by an electric spark, by red-hot metal, or by violent concussion. It does not ignite, however, by exposure to a temperature below redness. If subjected in an atmosphere of hydrogen or carbonic acid to a gradual increase of temperature, the sulphur may be completely separated, subliming upon the cool portion of the vessel.

It has been proved that powder may be inflamed, not only by the concussion of hard bodies, but by that of comparatively soft ones, provided it be sufficiently powerful. Experiment has shown that powder placed upon lead, or even upon wood, may be ignited by the shock of a leaden bullet fired at it.

No doubt the inflammability of a powder is greatly influenced by its physical state. A fine-grain powder will burn much more rapidly than powder of a larger grain. The greater the density, the more gradual is its combustion. Angular powder will burn more speedily than the round-grained, and the inflammability of powder is not only retarded by the presence of moisture, but also by the glazing.

Powder in which the theoretical proportions are exact, and in the manufacture of which a very inflammable charcoal has been used, the ingredients having

been mixed without the application of very great pressure, will undergo, when ignited, an almost instantaneous decomposition. Such a composition, in many respects, resembles the fulminates; the strain which it exerts upon the fire-arm is far too powerful; hence it is not so generally applicable as a more gradually disintegrating mixture.

Gunpowder always attracts more or less moisture, since charcoal, however dense, absorbs humidity from the air; though, of course, the hygroscopic property of powder is considerably increased by the use of porous charcoal in its manufacture, or by the presence of any considerable quantity of powder-dust. Powder, manufactured with perfectly pure nitrate of potassa, is found, if preserved in dry stores, to absorb about 0.5 per cent. of moisture; the amount naturally increases considerably if it is kept in a damp situation. Fine-grain powder is generally found to absorb moisture more rapidly than the large-grained.

The amount of ash left upon the ignition of gunpowder varies according to the purity of its ingredients, the proportions employed, and, more particularly, the nature of the charcoal used. Its gradual accumulation in a fire-arm is a source of great inconvenience, since it soon renders it foul and difficult to charge, thus limiting the number of rounds that can be fired in rapid succession, without cleaning out the instrument. This *fouling*, as it is termed, is avoided to some extent by the use of a small quantity of some fatty substance, which lubricates the barrel, and, by preventing the adhesion of the ash, promotes its expulsion by the gases as they make their escape.—*Abel and Bloxam*.

BISHOP affirms that gunpowder explodes exactly at the temperature of 600°. When exposed to a heat of 500°, its nature becomes totally changed; not only is the whole of the moisture expelled, but the saltpetre and sulphur are reduced to the fluid state. The powder on cooling is found to have changed from blackish-grey to an intense black; the grain has become extremely indurated, and by exposure even to very moist air, it then suffers no alteration by imbibing moisture.

The specific gravity of gunpowder, according to Dr. URE, as taken by him with five different kinds in oil of turpentine, varied from 1.793 to 1.80.

ANALYSIS.—The following is the ordinary method of analysing gunpowder:—

The water is first estimated by submitting a small portion, say three or four grammes of the sample to be examined, to a temperature of 212°, in a water-bath, until it ceases to lose weight. Some chemists prefer placing a known quantity over sulphuric acid *in vacuo*, but this method takes much more time, and the former is sufficiently accurate for all ordinary purposes. The loss after drying shows the amount of moisture in the sample, from which the per-centage may be readily calculated.

It may be well for the Editor to remark here, that the quantity of water should be a *mere trace*, if any. If it is found to contain several per cent. of water, it may be rendered again perfectly good by careful exsiccation.

The next step is the determination of the nitrate of potassa, which is effected by boiling the powder in

which the humidity has been determined, in about six times its weight of water; the residuum is then carefully collected on a tared filter, washed with tepid water until a few drops of the filtrate when evaporated upon platinum foil give no residue; the insoluble matter upon the filter being then desiccated at 212°, and weighed, the loss will indicate the amount of nitrate of potassa. The saltpetre may also be determined by evaporating to dryness the filtrate obtained as above, fusing the residuum at a low temperature, and then ascertaining its weight. Both these methods may be employed, the one thus furnishing a check upon the other.

Should the saltpetre contain chloride of sodium, as it ordinarily does, the amount of it may be determined as follows:—The dry and weighed residuum, procured as just described, is redissolved in water, and a little nitric acid and a weak solution of nitrate of silver added, when, if chlorides are present, a curdy precipitate of chloride of silver occurs; this is collected on a filter,edulcorated, dried, fused with great care in a porcelain crucible, and weighed. One gramme of the chloride of silver represents .407 chloride of sodium, or .247 of chlorine.

The amount of sulphur and carbon, respectively, may be ascertained by various methods.

One of these, devised by GAY-LUSSAC, consists in igniting in a platinum crucible a known quantity—say one gramme—of the gunpowder, with the same weight of carbonate of potassa and of nitrate of potassa, and four times the quantity of common salt; by this means the sulphur is oxidised into sulphuric acid, and may be determined as under:—The fused mass, which should be perfectly white, is dissolved in water, and acidified by means of hydrochloric acid. The solution is next filtered, and chloride of barium added so long as a deposit is occasioned. After some time, when the precipitate has subsided, the whole is filtered, and the sulphate of baryta aspersed with hot water, until sulphuric acid causes no turbidness in a portion of the washings. The precipitate is next dried, and then, as much of it as is possible being detached from the filter paper, the latter is burned in a platinum crucible until the whole of its carbonaceous matter is destroyed; the former introduced, heated to redness, and weighed. Each 116.5 parts of sulphate of baryta represent forty-nine parts of monohydrated sulphuric acid, and consequently sixteen of sulphur.

The per centage of moisture, nitrate of potassa, and sulphur being calculated, the difference indicates the amount of carbon.

WHITE GUNPOWDER.—AUGENDRE has described a new kind of gunpowder, consisting of one part of ferrocyanide of potassium, one part of white sugar, and two parts of chlorate of potassa. These are reduced to powder separately, and are then mixed with the hand. In experiments with small quantities, they may be pounded together in an agate mortar. Not the least fear need be entertained of the effects of the most powerful friction. In preparing it on a larger scale, the mixture is moistened with two or three per cent. of water, and triturated in a bronze mortar with a wooden pestle; fifteen minutes' pounding suffices for

small quantities, as the ingredients do not require such intimate admixture as in the preparation of ordinary gunpowder. The powder is granulated in the usual way, and dried in the air.

Gunpowder thus prepared is white; fires with the greatest ease, both in the granular state, and in that of an impalpable powder, by contact with an incandescent body; the flame with which it burns is greater than that of ordinary powder, and it leaves less residue. As taken from the mortar it is perfectly inflammable, so that there never need be any apprehension of its missing fire. It must be exceedingly dry for a violent blow of iron to explode it; friction between two polished bodies never produces this effect, nor does striking wood upon wood, or wood upon metal. It is formed of substances, the composition of which is well determined and fixed, and it can, therefore, always be obtained of the same strength. The materials are unalterable by the action of dry or humid air, so that they can be kept for any length of time, which cannot be done with the charcoal used for the ordinary article. The manufacture requiring less time, a fortress might, in case of necessity, be provided with the several constituents in powder, and the mixture made when required, by which means the danger attendant upon large deposits of gunpowder would be avoided. The force is much greater, so that there is space for a larger number of charges in the artillery caissons. The dust having the same effect as the grain, each constituent might separately be reduced to a very fine powder, and the whole commingled in a leather barrel.

But though possessed of all these superiorities over common gunpowder, it is not free from serious disadvantages, one of which is, that it oxidises iron barrels very much, and its use is consequently limited to bronze ones, and to the filling of hollow projectiles. It is more easily inflamed than common gunpowder, but not so readily as the other compounds of chlorate of potassa which have been prepared for the same purposes.

AUGENDRE directs attention to the circumstance, readily conceivable from the behavior of chlorate of potassa towards several other substances, that the greatest care should be taken to avoid introducing into the mixture any charcoal or sulphur, or mixing with it any ordinary gunpowder.

The proving of gunpowder, and many other subjects connected with the present article, are not of a sufficiently chemical nature to be treated of here.

STATISTICS.—Gunpowder is always packed in strong oak barrels, containing from eight to one hundred pounds each, the latter being the maximum weight allowed by Government to be contained in a single package. When for sporting purposes, it is in canisters and strong papers.

Owing to gunpowder being entirely free from duty, the returns of the Board of Trade can scarcely be expected to give even an approximation to the amount of imports and exports. Indeed, the import returns during the years 1850 to 1853 inclusive are entirely blank, while, for 1854, they are registered as one hundredweight, and in 1855, 11,851 hundredweights. During the years 1850-55 inclusive, there were no returns of exports.

GUTTA-PERCHA.—This valuable substance, the name of which is the same in all languages, and which was unknown in Europe previous to the year 1843, is the inspissated juice of a tree which grows in the Malayan forests and the islands of the Eastern Archipelago. In its origin, character, and composition, it is analogous to caoutchouc, but wants the peculiar elasticity of that substance; on the other hand, it possesses special and distinct properties, which render it applicable to an extraordinary variety of important uses, and which, within the short time that has elapsed since its introduction into Europe, have given a remarkable development to its manufacture.

It may not be out of place, even in a scientific work, to correct an erroneous mode of pronouncing the name of this substance, which has become very general. The name is a pure Malayan one, and not Latin, as might be supposed from a mere coincidence in the spelling—*gutta* meaning in the Malay language the gum or concrete juice of a plant, and *percha* the particular tree from which the juice is procured. Dr. MONTGOMERIE, its discoverer, states that the *ch* is not pronounced hard like a *k*, but like the *ch* in the English name of the fish *perch*; and that if a European were to inquire of a Malay for gutta *perka*, he would be told the thing was unknown, when perhaps plenty of the gutta-percha might be procurable by pronouncing the name properly. He adds, that had he thought there was a probability of the name being mispronounced, he might have used the uncouth orthography *pertscha*, but then it would have run the risk of being taken for a Russian or Polish appellation.

HISTORICAL NOTICE.—It appears that this substance, though only of recent introduction into commerce, was brought into England in the days of TRADESCANT, as a curious product, under the name of *mazer wood*; and subsequently it was frequently brought from China and other parts of the East, under the designation of india-rubber, in the form of elastic sticks, whips, and other trifling articles. The products of the East Indies, shown by the Honourable East India Company at the Great Exhibition, proved that the natives of the country in which the gutta-percha tree grows, knew also how to appropriate it to the manufacture of different kinds of vases, and that European industry and the wants of an advanced civilization have only developed its application to a greater variety of uses than were known or required in the countries to which it belongs.

The merit of first appreciating its value and making it known in Europe, is claimed by two individuals, who seem to have endeavored about the same time, and quite independently of each other, to bring it into public notice, namely, Dr. WILLIAM MONTGOMERIE, a Scotchman, for some years assistant-surgeon to the Residency at Singapore, on the Malay peninsula; and Sir JOZE D'ALMEIDA, who had been for many years resident in the same settlement. This last-named gentleman came over to England in the beginning of the year 1843, bringing several samples of the gutta-percha with him; and, among other channels of communication with the scientific world, had the honor of presenting specimens to the Royal Asiatic Society,

for which he received their letter of acknowledgment and thanks. On the whole, however, the merit of priority of discovery seems, by general assent, to be assigned to Dr. MONTGOMERIE, who, in point of fact, was not only the first European who discovered the value of the product, but the first who exerted himself actively and successfully to bring it into general use. Before the attention of this gentleman was directed to it, it was not only quite unknown to Europeans in general, but was known as an article of value only to a few of the inhabitants even of those localities in which it is produced, and was applied by the natives to very trifling uses; being chiefly employed to make handles for *parangs* or wood-choppers, as a substitute for wood or buffalo-horn.

The valuable qualities of the substance were no sooner publicly announced than it came into general demand. The immediate effect of its discovery may be compared to that of the gold-fields in California and Australia; and perhaps no substance except the precious metals has been more eagerly sought after or more highly appreciated. Its singular adaptation for an infinite variety of purposes was quickly recognized, and an extensive trade in it sprang up almost immediately. In the year 1844, previous to which its very name was unknown to European commerce, two hundredweight of it were shipped experimentally from Singapore. In 1845 the exportation of it from that port rose to one hundred and sixty-nine piculs—a picul being equivalent to 133·3 pounds; in 1846, to five thousand three hundred and sixty-four piculs; in 1847, to nine thousand two hundred and ninety-six; in 1848, to twelve thousand. In the first four and a half years of the trade, twenty-one thousand five hundred and ninety eight piculs of gutta-percha, valued at two hundred and seventy-four thousand one hundred and ninety dollars, were shipped at Singapore; the whole of which was sent to England, with the exception of fifteen piculs to Mauritius, four hundred and seventy to the Continent of Europe, and nine hundred and twenty-two to the United States.

The knowledge of the article, stirring the avidity of gatherers, gradually spread from Singapore, Northward, as far as Penang; Southward, along the East coast of Sumatra to Java; Eastward, to Borneo, where it was found not only at Sarawak, but also at Bruné and Pontianak on the West coast, and at Reti and Passir on the East.

This eager demand for the precious gum, animated by the thirst for immediate gain, was productive of a reckless destruction of the valuable trees that produced it. Instead of simply tapping the trees to obtain the juice, as is practised in the case of caoutchouc, the monarchs of the forest were felled to the ground; a magnificent tree of fifty or one hundred years' growth was cut down, the bark stripped off, and the milky juice collected and poured into a trough formed by the hollow stem of the plantain leaf; and some idea may be formed of the havoc thus made to procure the large supplies which were imported into Singapore, when it is stated, that on an average not more than twenty or thirty pounds were procured from one tree. The result was, that in the course of three and a half years,

two hundred and seventy thousand trees were felled, in order to get at the gum. It was, therefore, apprehended that the tree, although at first sufficiently plentiful, would soon become difficult to be procured; and this would undoubtedly have been the case, had not the Gutta Percha Company, subsequently formed in England, acted with a wise precaution, and embarked a considerable capital in seeking to promote the tapping, instead of the felling of the trees.

THE GUTTA-PERCHA TREE.—For some years after the introduction of gutta-percha, the character of the tree which produces it remained a mystery. At length from specimens which were sent home by Dr. OXLEY, in 1847, Sir W. J. HOOKER was enabled to refer the plant to Dr. WRIGHT's new genus of *sapotaceæ*, called by him *isonandra*; and accordingly he proposed to designate the gutta-percha plant *isonandra gutta*—the name by which it is now known. The tree is from forty to seventy feet high, and from two to four or even six feet in diameter. It is found all up the Malayan peninsula, as far as Penang, and its favorite localities are the alluvial tracts on the foot of hills, where it forms the principal portion of the jungle. In its general aspect, says Dr. OXLEY, it resembles the Durian—*Durio Zibethinus*, Linnaeus—so much so as to strike the most superficial observer. The trunk is straight; the leaves alternate; their upper surface of a pale green, and their under covered with a close, short, reddish-brown hair. The flowers are axillary, from one to three in the axils, supported on short curved pedicels,

Fig. 249.

and numerous along the extremities of the branches. The wood is described by HOOKER as peculiarly soft, fibrous, and spongy, pale-colored, and traversed by longitudinal receptacles of reservoirs filled with the gum, forming ebony-black lines. Fig. 249 is a portion of a branch of the gutta-percha tree, exhibiting also the leaves, flowers, and fruit.

There is no doubt that these are the characteristics of the tree from which the substance known as gutta-percha is obtained; but SEEMAN states that the gum termed by the Malays gutta-percha, is not the produce of the *isonandra gutta*, but that of a botanically-unknown tree, a species of *ficus*, and that the substance which has been improperly termed gutta-percha by Dr. MONTGOMERIE, and must now continue to be so called, is really the *gutta-taban*. It must ever be an object of regret, he remarks, that on the first introduction of the *taban gum*, its real name was not promulgated. The name, however, is now fixed beyond recall; and, to prevent misunderstanding, the reader has only to bear in mind that the substance known in Europe as *gutta-percha*, though stated by SEEMAN to be the *gutta-taban* of the Malays, is really the produce of *isonandra gutta* above-described.

EXTRACTION AND INSPISSATION OF THE GUM.—The sap or gutta circulates between the bark and body, in vessels, of which the course is well marked by black longitudinal lines upon the wood. To obtain the juice, it was formerly the practice, as already stated, to cut down the full-grown tree close to the root; rings were then made in the bark at distances of about twelve to eighteen inches apart, and a cocoa-nut shell, spathe of a palm, or such like receptacle, was placed under the fallen trunk, to receive the milky sap that immediately exuded upon every fresh incision. The quantity of gutta obtained from each tree so destroyed varied from five to twenty cattie; so that taking the average of ten cattie, it would require the destruction of ten trees to produce one picul, or one hundred and thirty-five pounds of gutta.

Fortunately, experience has now taught the natives that the milky juice may be collected by cutting notches here and there in the trunk of the living tree, and that in this way it may be preserved for future tapplings. This more economical method is rapidly gaining ground; and, considering the vast extent of territory occupied by the tree in its several varieties, and that European industry is now so deeply interested in its culture and preservation, there is little danger of the supply becoming exhausted.

The sap coagulates in a few minutes after it is collected; but before the crude gum becomes quite hard, it is kneaded by hand into compact oblong masses, from seven to twelve inches in length, by four or five in thickness. This part of the work is mostly performed by women, as represented in the annexed engraving—Fig. 250—which exhibits not only the ordinary appearance of the native Malays, but the character of the internal forest scenery of the tropical regions which they inhabit.

Dr. OXLEY's account differs somewhat from the preceding. He states that the sap, instead of coagulating and being made up into blocks on the spot, is collected in bamboos, taken by the natives to their houses, and boiled, in order to drive off the watery particles and inspissate it to the consistence it finally assumes. He adds, however, that although the process of boiling appears necessary when the gutta is collected in large quantities; yet, if a tree be freshly wounded, a small quantity allowed to exude, and it be collected and

moulded in the hand, it will consolidate perfectly in a few minutes, and have all the appearance of the prepared article. The apparent discrepancy between the

Fig. 250.

two statements may perhaps be explained by the fact, that Dr. OXLEY's account was written when the trees were uniformly felled to procure the juice, and when the latter was, therefore, collected in considerable quantities at a time, which rendered boiling necessary; whereas, when slowly collected in smaller portions from a number of living trees, the watery ingredient will evaporate as the juice exudes, and, with the assistance of kneading or moulding by the hand, that consolidation will take place to which Dr. OXLEY alludes as occurring in the case of small quantities.

PROPERTIES.—Gutta-percha, when quite pure, is of a greyish-white, but, as brought to market, it is more ordinarily found of a reddish-brown hue, arising from chips of bark that fall into the sap in the act of making the incisions, and which tinge it. It may be readily obtained in a pure state by dissolving the crude gutta in sulphide of carbon, filtering the turbid and brown solution under a bell-glass, and evaporating the filtrate by simple exposure to the air in a flat porcelain dish. After desiccation, the thin plate or cake of purified gutta is easily detached from the vessel by covering it for a few minutes with cold water, which destroys the adhesion. Nearly the whole of the extraneous tinctorial matter remains on the filter, with a portion of the undissolved substance.

Thus februated, the gutta is almost white, is semi-translucent in thin leaves, but opaque in thicker plates; it is greasy to the touch, and has a peculiar leathery

smell, somewhat similar to that of india-rubber. Its specific gravity, as determined by Dr. A. ADRIANI, was 0.999 at 68°, when subjected to the action of an air-pump to remove the adhering water-bubbles; without this precaution, it was only 0.728. A specimen of gutta-percha mechanically purified, and shaped in cakes, was found to have a specific gravity of 0.966°. The average density of the commercial article is 0.975°. The great variations in its density under different treatment imply a peculiar porosity in its structure, which was experimentally verified by PAYEN. Having placed a drop of its solution in bisulphide of carbon on a slip of glass, and allowed it to evaporate in the manner above-described, so as to obtain a thin film of the substance in a state of purity, he observed with the microscope numerous small holes or cavities, which were rendered still more visible by a drop of water; the liquid gradually insinuating itself, and rendering the film more opaque, while the cavities were observed, by means of the lens, to be enlarged. Similar results were obtained by keeping immersed in water for a considerable time, thin transparent laminae, obtained by the evaporation by heat of a solution of gutta-percha.

It was these observations which led this eminent chemist to conclude that the common commercial gutta-percha, retaining, in consequence of its porosity, a great many minute particles of air, owed to this circumstance its appearance of possessing a less density than that of water. In fact, on stretching gutta-percha under strong pressure, and immediately cutting the strips thus produced into very small pieces under water, the greater part of the fragments fell to the bottom of the vessel—some immediately, others absorbing a certain quantity of moisture. The same result was also obtained by keeping very thin leaves of gutta-percha, prepared by different methods, immersed in water deprived of air; their pores being gradually filled with the liquid, they became heavier than it, and then ceased to float. Gutta-percha is also heavier in proportion to the length of time it has been exposed to the air, particularly in thin leaves.

The porosity of gutta-percha, which allows a slow transudation of liquids through its mass, is the principal drawback to its use when formed into bottles or other vessels for holding chemical fluids. This porous structure becomes changed into a fibrous texture when it is drawn out so as to double its length; then, retaining little extensibility, it supports, without breaking, the action of a force equal to double that required for its elongation in the first instance.

Gutta-percha is a bad conductor of both electricity and heat. When rubbed it becomes negatively electric, and if dry, is an insulator equal in efficiency to shell-lac. Hence, among many other important applications, which will be noticed afterwards, its extensive employment in the covering of wires for the submarine telegraph.

But the great peculiarity of this substance, and that which makes it so eminently useful for many purposes, is the effect of heat upon it, applied either directly, or through the medium of boiling water. At ordinary temperatures it is a tough inelastic substance, and cold water has no effect upon it; from 32° to 77° it possesses about as much tenacity as thick leather, with rather

less flexibility; towards 120° it softens, and becomes sensibly doughy, although still very tough; and when raised above 150°, either by exposing it to the fire or by immersing it in hot water, it becomes soft and plastic, so as to be capable of being moulded to any required shape or form, which it retains upon cooling. Its ductility is such that, at a temperature of from 150° to 240°, it is readily extended into thin sheets, or drawn into threads or tubes; its flexibility and ductility diminish as the temperature becomes lower. It does not possess, at any temperature, the peculiar elastic extensibility which characterizes caoutchouc. When cold, it again becomes hard, and possessed of extraordinary tenacity.

It melts at 248°, and may be made to boil without acquiring a sensible color; the transparent fluid gives abundant vapors, which are condensable into a nearly colorless oily liquid. The portions last distilled have a brownish-orange hue, and a thin layer of carbonaceous deposit remains adherent to the sides of the vessel. Heated beyond this point, it is decomposed, yielding inflammable products; a strip of it cut off burns with a bright flame, emitting sparks, and dropping a black residuum in the manner of sealing-wax, which in its combustion it very much resembles.

Common gutta-percha is perfectly insoluble in water at any temperature; it effectually resists damp, and hence its valuable applications as a waterproofing material, and as a substitute for leather in soling boots and shoes. It likewise withstands the various influences which excite fermentation, but experiences a sort of doughy fusion when exposed to the direct action of the solar rays in summer. Soda and potassa, even when caustic and concentrated, ammonia, saline solutions of all kinds, water containing carbonic acid, the various vegetal and mineral acids, do not act upon it. It is not affected by fermented liquors, such as wines, beer, *et cetera*; even alcohol scarcely dissolves a trace of it. Olive-oil has no action upon it when cold, but when hot, it dissolves a small portion of it, which is again precipitated on cooling.

Concentrated nitric acid attacks gutta-percha rapidly with effervescence, and an abundant evolution of fumes of nitrous acid; the gutta is disintegrated, and colored of a brownish-orange red; it becomes doughy, and afterwards solidifies by degrees, but remains friable. Concentrated sulphuric acid produces the same effect more gradually, rendering it brown, and causing its disintegration, with a sensible evolution of sulphurous acid. MILLER affirms that hydrochloric and dilute hydrofluoric acids have no action upon it; hence it is employed in the preparation of bottles and vessels used for containing these liquids; but PAYEN states that hydrochloric acid, in its saturated solution in water at a temperature of 68°, attacks gutta-percha slowly, and gives it a more or less deep-brown color, at length rendering it brittle.

The same chemist remarks that, in the cold, and even by heat, not more than 0.15 to 0.22 of the gutta-percha is dissolved by anhydrous alcohol or ether; but ARPPE states that thirteen per cent. of gutta-percha is dissolved by alcohol, and that, separated from mechanical admixtures, it is *soluble in ether which is free from alcohol*,

whereas, *if it has been previously treated with alcohol, it does not dissolve in ether*. This observation, which seems to have been overlooked by M. PAYEN and other chemists, has an important bearing on the analysis of gutta-percha.

Benzol and oil of turpentine dissolve gutta-percha partially when cold, but almost completely by heat. One part of the gutta requires for its solution from four to six parts of oil of turpentine. Bisulphide of carbon and chloroform dissolve it cold, and by either of these solvents it may be obtained pure in the manner already described.

ELEMENTARY COMPOSITION.—Gutta-percha is, like caoutchouc, a carbide of hydrogen, and nearly isomeric with that substance, as the following analyses will show:—

	Gutta-percha.	Caoutchouc.
Carbon,.....	86.36	87.2
Hydrogen,.....	12.15	12.8
Oxygen,.....	1.49	—
	100.00	100.0

It is a question indeed whether the elementary composition of the two substances is not precisely the same, the small quantity of oxygen detected by Dr. MACLAGAN in gutta-percha being probably derived from the air during the process of purification. Its acknowledged porosity, and the difference in its specific gravity under different conditions, are facts which afford a strong presumption in favor of this view.

But like other isomeric substances, gutta-percha and caoutchouc, though strikingly similar in many of their properties, and more especially in their resistance to the action of most chemical agents, differ considerably in other respects, and this must be attributed to the different grouping of their elementary constituents, if not to the actual presence of oxygen as one of the essential ingredients of gutta-percha.

Professor PAGE states that gutta-percha, when rolled into thin sheets or drawn into ropes, comports itself like a fibrous substance, which is not the case with caoutchouc. A strip cut from a thin sheet of gutta-percha may be stretched considerably in one direction, that is, in a line with the fibre, but any attempt to stretch it across this is followed at once by a rupture. It is not so with a sheet of caoutchouc, which will stretch *equally well in all directions*. On examination of sheets of these two substances—so far believed to be *isomeric*—a marked difference of texture is at once perceived. The caoutchouc gives little or no change of color, while the gutta-percha exhibits a beautiful spectacle. It appears to be built up of prisms of every variety of hue, and, as it were, fused into each other. Professor PAGE states that it resembles more nearly some specimens of ice which he had examined, than anything else. The caoutchouc and gutta-percha must be kept under considerable tension during the examination.

PROXIMATE PRINCIPLES.—PAYEN states that purified gutta-percha is formed of three proximate principles, very different from each other as regards their properties, but isomeric as regards their elementary composition, and also isomeric with purified caoutchouc, being all of them carbides of hydrogen, and

each represented by the formula $C_8 H_7$. These three proximate principles, which he terms *gutta*, *albane*, and *fluavile*, he describes as being found in gutta-percha in the following variable proportions :—

	Centesimally.
Gutta,	78 to 82
Albane,	16 to 14
Fluavile,	6 to 4
	100 100

PAYEN commenced his experiments by submitting the gutta-percha to the action of alcohol. Reduced to thin leaves, it was treated, in a close vessel, with fifteen to twenty volumes of cold anhydrous alcohol; the heat was raised slowly, by means of the water-bath, to the point of ebullition, 172° , and kept at this temperature during several hours; the liquid was then filtered whilst boiling, and left in a closed flask, when it was found, at the end of from twelve to thirty-six hours, to begin to deposit on the sides of the vessel, and on the surface of the solution, white opaline granules, distant from one another, but some of them in groups; their size gradually increasing for some days. These granules, carefully examined under the microscope, were found to have the form of spherules truncated by the sides of the vessel. Their surface was either smooth or bristling with very small, transparent, elongated, lamellated crystals. Some superficial fissures appeared to indicate that these spherules were formed of a sort of transparent yellow nucleus, covered with a white pellicle; and PAYEN ascertained on examination that such was really their singular crystalline structure, of which perhaps no other example is known. He found also that cold anhydrous alcohol dissolved the whole of the yellow internal spheroidal substance, while the superficial pellicles, in the interior of which the alcohol had then substituted itself for the solid yellow globules, appeared consequently whiter and more transparent. The alcoholic solution, which had been for some days depositing this complex spheroidal crystallization, was again capable of taking by heat a further portion of the two proximate principles remaining in the substance, allowing a fresh quantity to crystallize on cooling, and thus to be developed respectively in the white pellicle and yellow nucleus. The extraction was completed by returning the boiling alcohol several times upon the gutta-percha till nothing more was dissolved.

The solid substance, which entirely resisted the action of the alcohol, possessed, with some modifications, the principal properties of crude gutta-percha; and this is what PAYEN termed *pure gutta*, or simply *gutta*. Of the two other organic principles developed by the method which he adopted, the *white crystalline resin* which covered the spherules was what he called *albane*; and the *yellow resin*, which was much more soluble in cold alcohol than the other, was the substance which he termed *fluavile*. The commercial varieties which he examined gave him the proportions above stated; their special properties were as follow :—

1. *Pure Gutta*.—It will be seen that the most abundant of the three principles distinguished by PAYEN is the so-called *pure gutta*, or that portion insoluble in

alcohol, and which is described by the same chemist as being insoluble in ether. M. PAYEN probably failed to effect its solution, from the circumstance that he employed the same gutta which had previously been treated with alcohol; in that case, according to M. ARPPE, it is not dissolved by ether.

PAYEN describes his *pure gutta* as presenting the principal properties of the commercial substance. It is white, transparent at a temperature of 212° , when all its parts are melted together; opaque or semi-transparent when cold, from its then acquiring a structure which causes the interposition of air, or of a liquid possessing a different refraction from its own. He states that this structure appears still more distinct than in the natural substance containing all these principles. In thin sheets, and at a temperature of 50° to 86° , it is supple, tough, extensible, but not very elastic. At 112° it softens and turns back upon itself, and becomes more and more adhesive and translucent in proportion to the elevation of temperature, undergoing a sort of doughy fusion, which becomes more distinct towards 212° to 230° . Heated beyond this point, it melts, boils, and distils, furnishing a pyrogenous oil, and eliminates carbides of hydrogen. Its behavior with acids, alcohol, and oils, chloroform and bisulphide of carbon, is the same as the commercial article.

After the extraction, by means of ether, of the two resins contained in the thin leaves of white or purified gutta-percha, leaving the last portion of ether with which they were impregnated to evaporate in the open air, these leaves, inclosed in a flask, experienced, after remaining there for two months at a temperature of from 68° to 82° , an alteration which appeared to depend on their porosity, the action of the air, and perhaps the ether retained in their pores. However it be, these leaves had then acquired new properties; they were brittle; exhaled a very distinct sharp odor; brought into contact with an excess of anhydrous ether, they were partially dissolved; the soluble portion obtained by the evaporation of the ether, and exsiccation at 194° , was glutinous and translucent; it became opaque and hard by cooling down to 14° .

The same chemist states as a fact which he had personally ascertained, that thin leaves, exposed for eight consecutive days to the action of the sun in moist air, were discolored, and that their substance had become in great part soluble in ether.

2. *Albane*.—The albane, or crystalline white resin, presents itself as a light pulverulent mass, apparently opaque, which, under the microscope, exhibits thin transparent lamellar crystals. From 32° to 212° it does not experience any sensible change; its fusion commences at 320° ; at 347° to 356° it acquires an oleiform fluidity and complete transparency, without any noticeable color; it solidifies on cooling, shrinks, which causes it to split, and remains transparent and a little heavier than water.

The crystalline resin is not attacked or readily moistened by either cold or boiling water; or by hot or cold caustic alkaline solutions, ammonia, and the various dilute acids. Monohydrated sulphuric and nitric acids attack it rapidly, producing similar phenomena to those observed in their action upon pure gutta.

Hydrochloric acid, on the contrary, does not act upon the white resin.

3. *Fluavile or yellow resin.*—This amorphous transparent resin, of a lemon or orange color, according to its thickness, is a little heavier than water, solid, and even hard and brittle at 32°; it gradually becomes more flexible in proportion as the temperature is raised; at 122° it becomes pasty; it does not become completely fluid below 212° to 230°. Heated beyond this point it boils, but then gradually undergoes considerable alteration, becomes brown, and evolves acid fumes and carbides of hydrogen. It strongly retains the alcohol in which it has been dissolved; but is separated from it by heating *in vacuo* to 212°, until bubbling entirely ceases.

This resin is soluble in the cold in alcohol, ether, benzol, turpentine, bisulphide of carbon, and chloroform: all these liquids, when evaporated, leave as residue the amorphous resin. Dilute acids, concentrated alkaline solutions, and ammonia, do not attack the yellow resin. Monohydrated sulphuric and nitric acids act upon it rapidly, producing phenomena analogous to those exhibited with the other two principles. Hydrochloric acid, even in its saturated solution at 68°, is without action upon it. But the most remarkable character of this resin is the power of forming, under the circumstances already indicated, those globose crystals covered with a white pellicle of another resin, and presenting in their complex form the appearance of opaline spherules.

MANUFACTURING PROCESSES.—It has been stated that the gutta-percha, after its extraction from the tree in the form of a milky juice, is first allowed to coagulate, and then made up into lumps or blocks of some pounds' weight. These, as they arrive in Europe, are far from being pure, for besides containing chips of bark, leaves, and other adventitious substances which fall accidentally among the juice, the natives make no scruple of introducing stones, earth, and other rubbish, to increase the weight of the blocks. The first and most essential process in the manufacture of gutta-percha is, therefore, its purification; and in fact, ever since its introduction into Europe, gutta-percha has found everything provided for the purpose of cleansing it, being worked by processes and instruments very similar to those which had been previously employed in the purification of india-rubber. It is also vulcanized, and cut or moulded into different shapes, in much the same manner. The general nature of the operations may be briefly described as follows:—The blocks of gutta-percha being first cut into slices by revolving knives, are softened by means of hot water, and then divided and torn into shreds by the same machine that is used for india-rubber, which serves also to knead the gutta-percha in such a manner that the crushed stones and earth may be separated from it on being diluted in the water; it is then dried, and submitted, by means of a powerful machine, to a mastication similar to that which caoutchouc is made to undergo; and when, after some hours of kneading, the mass has become homogeneous and sufficiently softened, it is extended by the drawing-mill into cylindrical cords, moulded into tubes of various diameters, or spread out by means of the flattening machine into sheets of dif-

ferent thicknesses, which are finally divided into bands or slivers, and from these are cut out with a nipping tool the pieces which are required to be employed in different uses.

These various operations, together with the vulcanization of gutta-percha, will now be described successively and in detail—premising that in this country the manufacture is confined to two or three companies, which work the various patents secured from time to time by Mr. HANCOCK and others. A simple description of the manufacture, as conducted by the London Gutta-Percha Company, will, therefore, embrace all that is really important in the different operations.

PURIFICATION.—*The Cutting Machine.*—When a visitor enters the works of the Gutta-Percha Company, he observes in the yard or court the imported blocks of the raw material piled in great heaps. These blocks, when they are required for use, are first taken from the heaps to the cutting or slicing machine, which is a large solid vertical disc of iron, armed on one side with sharp knife-edges, and revolving at the rate of two hundred turns per minute against the extremity of a sloping iron table. The block of gutta-percha being brought to the edge of the table, is rapidly caught by the knives, and literally reduced to shavings, which fall into a receptacle beneath.

Fig. 251.

Fig. 251 is a side elevation of this machine, and Fig. 252 a front elevation of the disc, with part of the frame. The revolving disc, B, is a circular iron plate, of about five feet diameter, into three slots in

Fig. 252.

which are inserted three radial knives, *b*, *b*¹, *b*², in a similar manner to the iron of an ordinary plane or spoke-shave. Supported by the frame *AF* is the shaft *D*, to one end of which the plate *B* is attached, and to the other the strap-pulleys *EE'*, by one of which motion

is communicated to the shaft from a steam-engine, or any other convenient first mover. *c* is an inclined shoot, down which the lumps of crude gutta are dropped against the knives of the revolving disc, and are cut into slices of a thickness corresponding to the degree of projection given to the knives.

The knives are represented in Fig. 252 as being straight, but Mr. HANCOCK, the patentee, states in his

Fig. 253.

specification, that where the gutta-percha to be cut happens to be of a more than usually hard or intractable character, he finds it advantageous to substitute knives of a curved or reaping-hook form, on account of their more gradual mode of action. The machine, which is

Fig. 254.

put in motion at the Gutta-Percha Company's works through the agency of two fifty horse-power engines, is represented as in operation in Fig. 253; and it may be remarked, in passing, that the stones and other

adulterative materials which the cupidity of the Malay gatherers has added to the mass, are often discovered by this process, very much to the injury of the cutters.

First Boiling and Teasing.—Having been reduced to shavings, the gutta-percha must next be perfectly cleansed of the dirt, leaves, and other extraneous matter. This is effected by throwing the shavings into a large tank containing water, as shown in Fig. 254, to which the waste steam of the engine is conveyed, for the purpose of boiling. This process softens the whole into a fluid mass, and separates the more considerable impurities, which, by the agitation of the boiling, sink to the bottom. The greater part of the rubbish having thus subsided, the partially-purified gum is collected into one mass, and carried to what is called the *teaser*—a sort of large circular box, containing a cylinder or drum covered with rows of bent jagged teeth. Two of these machines are represented in the same figure. Revolving at the rate of about eight hundred turns in a minute, the teaser quickly tears the mass into shreds, which fall into a vat of water beneath. Here the gutta-percha, being in its naturally porous state lighter than water, floats upon the surface, while the impurities disengaged from it by the action of the teaser fall to the bottom. The gutta-percha is now cleansed from all impurities; it has a crisp and fresh-looking appearance, and is ready for the next operation, which consists in working and kneading it into a homogeneous mass.

Second Boiling and Kneading.—The operation of teasing is followed by a second boiling, which has the effect of blending the fragments of the now purified substance into a warm soft mass, and in this state it is introduced into the *kneaders* or *masticators*, which are thick, strong, circular iron boxes, about three feet long and a foot and a half deep, containing revolving cylinders armed with cogs or pins on their surface. The cylinders and their containing boxes are of cast-iron, and are heated by steam. The gutta-percha, when introduced, is thus kept in a soft state, and being carried round by the action of the revolving cylinders, it is forcibly squeezed against the sides of the box; while, by the action of the cogs or pins, every air-bubble is expelled, and the whole is brought to a perfectly homogeneous mass of uniform consistency, without a particle of water in its composition.

In April, 1853, a patent was taken by Mr. NICKELS for using two rollers with screws on their surfaces, in place of teeth or projections, for masticating or kneading. The rollers work parallel, and nearly up to each other; and in each of the threads of the screw-rollers there are notches, which the patentee prefers to be made in a diagonal direction. This form of machine is considered the most effective, and is now most commonly used.

ROLLING INTO SHEETS.—In the state in which the gutta-percha comes from the kneading or masticating machine, it is ready for being manufactured into different shapes, and, with this view, it is now rolled into sheets, or pressed out into tubes. The first operation is required to prepare it for its subsequent conversion to most of the useful and ornamental purposes to which it is applied; and, with this view, the kneaded mass is

carried to the *rolling machine* represented in Fig. 255. This apparatus is similar to that employed in paper-mills, the gutta-percha, like the soft paper, passing on

Fig. 255.

an endless band between steel cylinders placed at the requisite distances apart, according to the thickness of the sheet required. By means of screws the cylinders can readily be adjusted to produce with equal ease the stoutest driving band, or the thinnest *gutta-percha tissue*, so successfully employed as a substitute for oiled silk, hydropathic bandages, *et cetera*. After passing between the rollers in a soft and impenetrable state, the sheet performs a long journey on the endless band, in the course of which it gradually cools and hardens, and finally appears at the other end a smooth, firm, flat sheet, which admits of being received and wound on a drum till the requisite length has been worked off. If, however, the sheet be too thick to cool sufficiently by merely travelling the prescribed distance, it is ventilated, as it passes along, by a series of fans like those of a winnowing machine.

DRAWING RIBANDS AND CORD.—When the material is required to be in bands or strips, it is generally cut into that form, while being rolled into sheets, by a series of knives so placed as to divide the sheet while yet plastic into any number of bands of the required width, just before quitting the rolling machine. The knives are set upright in a frame, edge foremost, at the requisite distances from each other, and, without interrupting the progress of the sheet, they slice it into bands, which, as before, are made to travel till they cool, and are then wound upon a drum.

In 1847, an ingenious machine was patented by Mr. CHARLES HANCOCK for cutting gutta-percha into narrow ribands, and manufacturing it into thread or cord of any required shape. A front elevation of as much of this machine as is necessary to understand its construction, is given in Fig. 256, in which *x y* are two grooved rollers, made of steel or iron, and mounted in suitable framework. The grooves of each roller are semicircular, so that when the grooves of one roller are brought opposite to those of the other, they form together a series of circular holes, as shown in the

figure, at the line of contact between the two rollers. The under roller is flanged at both ends, and the two ends of the upper roller are made to fit inside of these flanges, in order to keep the cutting edges from shifting or being damaged. From the prime mover, motion is communicated to the toothed wheel, *z*, on the shaft of the roller *x*, and thence through the wheels *t* and *u*, to the roller *y*. To cut thin sheets of gutta-percha with this machine into narrow strips or ribands, the material is passed through it cold, and only the cutting edges are brought into operation. To make round thread or cord by means of it, a sheet of gutta-percha, of a

Fig. 256.

thickness equal to the diameter of the holes formed by the grooves of the rollers, is passed through it at a temperature of about 200°, by supplying the material from a feeding chamber, heated to that degree by steam or otherwise; and the threads or cords, after passing between the rollers, are received in a tank of cold water, from which they are wound on reels or drums, conveniently placed for the purpose. Or, by another method, the gutta-percha is employed in a plastic state, and passed towards the machine under a gauge, after the manner employed in the caoutchouc manufacture.

Should it be desired to produce cord of a semicircular section, the lower grooved roller is replaced by a plain roller; or should cord of a form neither circular nor semicircular, but square, triangular, hexagonal, or of any other angular form be required, two cylinders are employed, grooved in such a manner as to produce the desired shape.

Cord and thread are likewise manufactured by means of a stamp, bearing a number of close parallel sharp edges, which are brought down upon a sheet of gutta-percha so as to cut it nearly through in a series of corresponding parallel lines. The narrow slips are then severally torn off, and polished up by hand for use.

CUTTING, SHAPING, AND MOULDING.—Besides the operations above-mentioned, the gutta-percha, when formed into sheets, admits of an infinite variety of applications. Softened by boiling water or steam, it may be shaped into any required form by the hand, the knife, the mould, and the press. The numerous workshops in the establishment of the Gutta-Percha Company are crowded with men and boys engaged in various operations. One apartment is occupied as the cutting and stamping room, and here the paper-cutting machine, invented by Mr. WILSON, is brought into extensive use, while moulds of every description are being employed to produce the different articles. If shoe-soles are required, the cutting machine is brought down upon a pile of stout broad bands, dividing a dozen of them at one operation into rectangular pieces, which are afterwards cut *en masse* into the required

shape by means of a sharp-edged frame. In one place are seen revolving tables, bearing inverted iron moulds, from which workmen are turning out buckets, bowls, bottles, and mariners' hats, while others are moulding bosses for flax-mills, rings, whips, *et cetera*. In one apartment cisterns and trunks for emigrants are being lined; in another, ornamental mouldings, medallions, pen-trays, ink-stands, picture-frames, and other fancy articles, are stamped from electrotype copper dies or wooden moulds. For the stamping or moulding, the sheets are cut into pieces, and each piece is warmed sufficiently to take the impress of the die.

GUTTA-PERCHA TUBING.—Perhaps the most important use to which gutta-percha has been applied is that of tubing, in which form it is extensively used for pump-barrels, ship-pumps, feed-pipes for locomotive engines, siphons for mines, suction or ejection pipes for fire, garden, and washing engines; and, being unaffected by acids, it is also available in this form for bleaching with chlorine and other chemical purposes. Accordingly, while the process of sheet-rolling, already described, forms the basis of a large department of the manufacture, the making of tubes constitutes another important and distinct department—the tubes being formed directly from a softened mass of the purified material, which has passed through the kneading or masticating machine. The process, while highly inge-

nious, is exceedingly simple. The softened material is forced by a piston through a steel cylinder, terminating in a mould that consists of a solid circular piece of metal set within an iron tube, the space between the two being the thickness required. The gutta-percha thus leaves the mould in a tubular shape, but would immediately collapse unless subjected, until it cools, to an even pressure both within and without. To accomplish this, it is received from the mould into a canal of water about fifty feet in length, along which it travels, being wound off upon a drum at the other end. The water, filling the interior, and pressing equally upon the outside of the tube, preserves it in perfect shape while it speedily cools it into hardness. The feeding cylinder is so contrived as to admit of being constantly replenished with new material, so that a tube of one thousand feet has been manufactured without a single break, being the longest ever made in one piece of any substance whatever.

COATING TELEGRAPH WIRES.—Another application of gutta-percha, which may vie in importance with that of tubing, though not of such varied usefulness, is that of covering wires for telegraphic purposes. In this respect its high insulating power, combined with its flexibility and imperviousness to water, render it of essential service; and, indeed, it may be doubted whether the submarine lines of telegraph, uniting dif-

Fig. 257.

ferent nations, islands, and continents, could have existed at this day without the valuable assistance rendered by gutta-percha. Its introduction into Europe, contemporaneously with the inauguration of these magnificent projects, by which the earth is being girdled with wires of living intelligence, can scarcely be re-

garded otherwise than as an express dispensation of an overruling Providence to advance the progress of civilization and human happiness. A good piece of gutta-percha, says Dr. FARADAY, will insulate as well as an equal piece of shell-lac, whether it be in the form of a sheet, a rod, or filament; but being tough and

flexible when cold, as well as soft when hot, it will serve better than shell-lac in many cases where the brittleness of the latter is an inconvenience.

A thin coating of gutta-percha may be communicated to a wire by drawing it through a glass or metal tube, filled with gutta-percha in solution, or rendered fluid by heat; but for the conducting wires of the electric telegraph, whether intended to be buried in the earth, or to form the core of a submarine telegraph cable, the coating, to insure perfect insulation, must possess considerable thickness, varying from one-sixteenth to upwards of one-eighth of an inch.

Accordingly, telegraph wires are now coated in much the same manner, and by mechanism much the same in principle, as that employed for moulding tubes. This will be seen from the preceding woodcut, Fig. 257, which exhibits in actual operation the machinery employed by the Gutta-Percha Company for coating the wires of the great Atlantic cable. The central conducting wire of this cable is *a strand* made up of seven wires of the purest copper of the gauge known in the trade as No. 22; it is about the sixteenth of an inch in diameter, and is formed of one straightly-drawn wire, with six others twisted round it. This strand received a coating of three separate layers of refined gutta-percha, which together bring its diameter up to about three-eighths of an inch. The gutta-percha employed for this great work was prepared with the utmost possible care. Lumps of the crude substance were first rasped down by a revolving toothed cylinder, placed within a strong hollow case. The raspings were then passed between rollers, macerated in hot water, and well agitated. They were next washed in cold water, and then, by means of a hydraulic apparatus, driven at a boiling water temperature through wire-gauze sieves, attached to the bottom of hollow vertical cylinders. Emerging from the sieves in plastic masses of exceeding purity, the gutta-percha was then submitted to the powerful action of the masticators already described, to expel from the purified substance the last traces of water, and to render it sound, compact, and homogeneous throughout. When thoroughly masticated and kneaded, it was then introduced into the horizontal cylinders, shown in the drawing; and through these, which were heated by steam to keep the gutta-percha in a uniformly soft and plastic state, it was squeezed by means of screw pistons, worked down slowly but resistlessly by the machinery. Under this pressure the gutta-percha emerged, as in tube-moulding, through a die, which received the termination of two cylinders, and which at the same time had the strand of copper wire moving along through its centre, instead of being stationary like the mandril in tube-moulding. The strands were drawn forward between the cylinders and through the die by a revolving drum. They entered the die in the form of bright copper wire, and issued from it like brown tubes or cords of gutta-percha. Six of these strands are represented in the drawing as being coated together, ranging along side by side; and this operation was repeated a second and third time, to produce what is termed *the core* of the Atlantic cable.

PATENT MOULDING.—In March, 1855, a patent was

taken by Mr. CHARLES GOODYEAR for ingeniously extending the principle of the apparatus above-described to moulding of every description; in other words, the machine which he employs is constructed in a similar manner to those now employed for coating telegraph wires, and for moulding tubes. Like these, it consists of a cylinder or barrel, into which the gutta-percha is introduced, and into the cylinder or barrel a piston works, being operated on by a screw or rack-and-pinion, or otherwise. In this case, also, the cylinder is enveloped in a steam-jacket to keep the contained material at a suitable temperature, and in the end of the cylinder is formed a nozzle or orifice, through which the contents are *forced into the mould* by the motion of the piston. The moulds are constructed of two or more pieces of metal, which are held together with bolts and nuts; they are formed with a suitable interior configuration for producing the article desired; and there are two or more passages which lead into the cavity, the largest of which is for the purpose of allowing the plastic substance to pass into the mould, and the others for allowing the air contained in the mould to escape. When the piston advances, it forces the gutta-percha from the barrel or cylinder into the mould, until it begins to escape from the air orifices. The piston is then arrested, and the mould, when removed and emptied, is ready to be again filled.

VULCANIZED GUTTA-PERCHA.—Among other properties in which gutta-percha strikingly resembles caoutchouc, is the change which it undergoes when intimately mixed with sulphur or its compounds, and afterwards submitted to a somewhat elevated temperature in close vessels. By this *vulcanizing* treatment, as the process is termed, it is rendered, like caoutchouc, less readily affected by changes of temperature, and more permanently soft and elastic, so as to be better fitted for bands and other purposes. To effect this remarkable modification, it is subjected to precisely the same methods of treatment as caoutchouc, and, indeed, it is frequently combined with that substance to give it the pliancy and elasticity required for some of its applications. Accordingly, most of the patents which have been taken in connection with this subject, are not confined to gutta-percha, but embrace also caoutchouc and various combinations of these with each other, as well as with other substances.

In Vol. I., pages 448 and 449, of this work, there are two methods described of vulcanizing caoutchouc—one of which consists in kneading it with sulphur or its compounds; the other, in immersing it in liquid compounds which hold sulphur in combination, and afterwards, in both cases, exposing it to the requisite heat. Gutta-percha may likewise be vulcanized by either of these methods, or by exposing it to the action of a mixture of steam and sulphurous vapors in HANCOCK'S apparatus, which was patented in 1847, and is figured and described at the pages above referred to.

In March, 1846, Mr. ALEXANDER PARKES of Birmingham obtained a patent for vulcanizing caoutchouc and gutta-percha, by dissolving it in bisulphide of carbon, coal-naphtha, turpentine, or any other suitable solvent; preferring, however, the bisulphide of carbon for the purpose, along with chloride of sulphur. The caout-

chouc or gutta-percha, when taken out of the solution, is suspended in a drying-room or stove, heated to about 80°; and, when the solvent has evaporated, the gutta-percha is well washed in water, or boiled for one hour in a solution of caustic potassa or soda, containing one pound of the alkali to a gallon of water. The gutta-percha being then dried, is ready for use.

Mr. HANCOCK, in the specification of his first patent, of November, 1846, recommended the sulphurizing of gutta-percha by means of sulphides, such as orpiment or liver of sulphur, in preference to sulphur itself; and in that specification he stated, that though a portion of sulphur might be used in place of an equal portion of sulphide, yet he considered the use of sulphur to be altogether objectionable, because of its offensive smell and tendency to efflorescence. Subsequently, however, he ascertained, as stated in the specification of his second patent, of date February, 1847, that if a very minute portion of sulphur be used along with a sulphide, a better result is obtained from a combination of the two than from either substance alone. The proportions which he found best in practice were six parts of sulphide of antimony, sulphide of calcium, or some other analogous sulphide, and one part of sulphur, to every forty-eight parts of gutta-percha. When the mixture of these materials has been effected, he places the compound in a boiler, and raises it, under pressure, to a temperature of 260° to 300°, in which state he leaves it for a period varying from half an hour to two hours, according to the thickness of the materials; by which time it becomes completely vulcanized, or, in other words, *metallo-thionized*.

In August, 1851, a patent was taken by Mr. STEPHEN MOULTON, for applying to gutta-percha his process for vulcanizing caoutchouc with hyposulphite of lead, to which allusion has been made in the article CAOUTCHOUC, Vol. I., p. 450. The same process is applied to a combination of equal parts of gutta-percha and caoutchouc, as to either of these alone; and when it is desired to produce a hard-cured gutta-percha, or a hard composition of gutta-percha and caoutchouc, described by the patentee as similar to horn or ivory, he adds from two to twelve ounces of calcined magnesia to each pound of gutta-percha composition, alone or combined with caoutchouc. The whole is then exposed in a close vessel to steam or dry heat of from 250° to 300°, for a period of time which will vary from two to ten hours, according to the thickness of the material and the quantity of goods introduced in one mass. The patentee adds, that after the gutta-percha goods, whether in the form of coated cloth, sheet gum, moulded, or any other article, have undergone this process, which he terms *curing*, they will be found not only impermeable to wet, but extremely tenacious, possessing the elastic property of the cured caoutchouc, and also unaffected by changes of temperature.

In December, 1856, a patent was taken by Mr. EMORY RIDER of London, for improvements in the method of vulcanizing gutta-percha; the principal novelty of which consists in the addition of one part of sulphur, or an equivalent thereof in some of its compounds, and *one part of litharge*, to sixty-six parts of the gutta-percha, prior to the exposure of the latter to

a temperature of 235° to 245°, for the purpose of expelling the volatilizable ingredients. The sulphur or hyposulphite of lead or zinc, or the artificial sulphide of lead, or other compound of sulphur employed for this purpose, is first mixed with the gutta-percha, and then thoroughly incorporated by passing the mixture repeatedly between metallic rollers heated to a temperature sufficient to make the gutta-percha very soft, and easily kneaded or worked. The mode of effecting this, which Mr. RIDER states that he has found to be most beneficial in practice, is by the employment of a machine in which the rollers work at different degrees of speed, and produce a teasing or grinding action, which he regards as of considerable importance in working the material. After being thoroughly incorporated and ground, the material is placed in a strong metal vessel, which is filled to about one-third of its capacity, so as to leave ample room for the swelling or expansion of the compound under the action of heat. It is then exposed to a temperature of about 235° to 245° for about three hours, and for this purpose the patentee prefers steam-heat, by which he is enabled to subject the gum under treatment to a greater pressure, and to obtain a more regular degree of heat than by other means. He adds, that the gutta-percha, having undergone this preliminary heating, may be vulcanized by the application of a much lower degree of heat than has been ordinarily used in that process, and that he has found a temperature of 255° to 265° to be sufficient to effect the change.

RENOVATION OF VULCANIZED GUTTA-PERCHA.—The fact that caoutchouc or gutta-percha, or compounds of these substances which have undergone the change produced by the vulcanizing process, can in that state be only very partially acted on by solvents, and with difficulty wrought by any of the usual means employed when operating upon the natural substance, renders it necessary to mould and finish the articles before they are submitted to this process, or to vulcanize them in the moulds, having previously mixed the gutta-percha with the sulphur in the kneading or masticating machine. By the process of vulcanizing, properly so called, is meant the subsequent heating, which can be applied in the act of moulding, when the articles require to be submitted to that operation.

But that very circumstance which renders it impossible to shape or manufacture gutta-percha into new forms after it has passed through the vulcanizing process—namely, the difficulty of acting on the vulcanized material either by means of heat or the usual solvents—must entail a considerable loss in the shape of waste, unless it be possible by some expedient to renovate the vulcanized gum, and restore it to its original state. It was stated in the article CAOUTCHOUC, Vol. I., p. 448, that the separation of the sulphur from that substance presented so many difficulties that it had not yet been accomplished. It may here be remarked, however, that several attempts have been made to effect this desirable object, and that, so early as in 1846, Mr. PARKES proposed and patented a method which is attended with partial success. According to this method, eight or ten pounds of the waste-cuttings, or old and worn articles, either of caoutchouc or gutta-percha, are

boiled in twenty pounds of the chloride of calcium, for a longer or shorter period according to the thickness or bulk of the substance, until, by testing a few of the pieces, it is found to be in a state to be readily united by pressure. It is then removed from the bleaching liquor, and washed, first in a hot alkaline water, and afterwards in pure water, also hot, when he states that the substance may be re-manufactured, and again submitted to either of the vulcanizing processes already described.

In January, 1856, a patent was granted to Mr. NATHANIEL SHATTSWELL DODGE, for a method which is stated to be more effective, and by which, in the words of the patentee, scraps or waste pieces of vulcanized india-rubber, or vulcanized gutta-percha—such, for example, as old shoes, railway-buffers, carriage-springs, *et cetera*—may be rendered fit to be re-used or worked up into useful articles or fabrics, *without requiring to be re-vulcanized*. For this purpose, the material to be treated, if existing in large pieces, is reduced into smaller ones, and is then placed in a vessel capable of being hermetically closed or made air-tight. To this material is now added pure alcohol—*alcohol absolutus*—and bisulphide of carbon, in the proportion of a quarter of a pound of the former and ten pounds of the latter to one hundred pounds of the material, the alcohol and the bisulphide being previously mixed together, and then poured over the material to be treated. The vessel containing the ingredients is then closed air-tight, and allowed to remain so for about two hours, more or less, at the expiration of which time the cover may be removed, when the whole, says the patentee, is found to be in a soft, plastic, or gummy state, and ready to be ground in the ordinary way of grinding such gums, for the purpose of manufacturing it into various useful or ornamental articles without repeating the process of vulcanizing. By adding a larger proportion of the alcohol and bisulphide of carbon, the gums may be reduced to a liquid state. The relative proportions of the two may, however, be varied according to circumstances, and the effect which it is desired to produce.

VARIOUS COMPOUNDS OF GUTTA-PERCHA.—In addition to that combination of gutta-percha with sulphur or its compounds, which, with the subsequent exposure of the material to a high temperature, constitutes the process of vulcanizing, a great variety of patents have been taken for combining this substance with other materials to render it softer or harder, more or less elastic, or more durable, and so to fit it for one or other of the almost innumerable purposes to which it has been proposed to apply it. To enumerate the whole of these patents in detail, so as to describe with precision the various processes and applications proposed, would both exhaust the patience of the reader and exceed the limits of this work. It is necessary, however, to give an abstract of the most important of these patented compounds and processes, to prepare the reader for a subsequent enumeration of the wonderful variety of uses to which this valuable substance has already been rendered subservient; and, in doing so, the Editor conceives that the best arrangement he can adopt is to follow the order of dates:—

Mr. HANCOCK's patent for January, 1846—the first patent taken on the subject—embraced a claim for making a compound elastic water-repelling substance, for manufacturing purposes, by mixing gutta-percha with jintawan, a somewhat similar material then recently imported from the East Indies, and also with caoutchouc, or with both, in proportions varying according to the softness, stiffness, pliancy, or extensibility which it was proposed to give to the compound. He states in his specification, that a good composition for bands or tape is formed by combining fifty parts of gutta-percha, twenty-four parts of jintawan, twenty of caoutchouc, and six of orpiment. These are incorporated together in the masticating machine, and the combination is facilitated by moistening the mass with rectified oil of turpentine, or some other solvent. The orpimented or sulphurised compound is then exposed to a heat of from 300° to 340°, for a period varying according as the temperature is higher or lower. With a heat of 300° about sixty minutes are required; while fifteen minutes are sufficient for a temperature of 340°. The required heat may be obtained either by means of high-pressure steam, or of water heated under pressure, or of hot air.

Another claim embraced in Mr. HANCOCK's first patent consisted in a method of improving gutta-percha in softness and pliancy, as also its combinations with caoutchouc and jintawan, supposing the substance, whether single or compound, to have been previously sulphurised. For this purpose, he subjects the article, whether in the state of blocks, sheets, threads, or any other form, to the action of sulphurous acid, either by exposing it to the acid in the state of vapor, or by steeping it in water impregnated with the acid, or by spreading over the article a paste made of sulphuric acid and ivory, or bone-dust, or animal charcoal, and then placing it in a steam-heated vessel or chamber.

Another method of producing the same effect—claimed also in the same patent—consists in adding to the gutta-percha and its compounds when passing through the masticating machine, and whether they are mixed or not with orpiment or any other sulphide, about ten per cent. of vegetal wax or tallow.

In October, 1847, a patent was taken by Mr. THOMAS FORSTER, for combining gutta-percha with animal charcoal, hydrate or milk of sulphur, ground whalebone, fragrant essential oils, musk, tonquin beans, orris root, or gum-benzoin, and for applying all or either of these ingredients, alone or in combination with caoutchouc or other matters, to fabrics or leather for clothing, lining for railway carriages, cart and rick covers, wrappers for goods, *et cetera*. For this purpose the gutta-percha is first cleansed or purified, and then put into a hot masticating pan with one or more of the substances above-mentioned, in the proportion of four parts of the gutta-percha to one of animal charcoal; or four of gutta-percha, two of india-rubber, and two of animal charcoal. The latter should be of the finest description, and carefully sifted through a very fine sieve. When these matters are thoroughly incorporated, a portion of any solvent is to be added—by preference, oil of coal—in such proportions as are needful for the particular fabric to be coated. The patentee found

equal weights of each to be good proportions. When the gutta-percha and solvents are well combined by heating them in a vessel enveloped in a steam-jacket, and are in a fit state to be spread upon the fabrics, Mr. FORSTER adds orris root or other perfumes in such proportions as are necessary to give the goods the desired scent; but if caoutchouc is a component part of the compound, he says it is best to use orris root, tonquin beans, musk, or gum-benzoin only, as the fragrant essential oils are apt to act injuriously upon the rubber in the course of time. For coarse goods, such as carriage covers and the like, he takes gutta-percha four parts, ground whalebone and hydrate of sulphur, each one part, and one-sixteenth part of any mineral preservative of vegetal matter—by preference, arsenic—works the whole in a mastrating pan, and afterwards spreads it upon the fabrics, with or without a solvent. If the fabrics are required to be of any particular tint, he adds to any of the above compositions the color necessary to produce it.

In forming such articles as are required to resist moisture, as buttons, tea-trays, military ornaments, *et cetera*, he first saturates the fabrics with any water-repellent matter, preferring for this purpose boiled linseed oil, dries them thoroughly in a stove, and then coats them with the first-mentioned composition of gutta-percha. In making panels for carriages, doors, boxes, *et cetera*, he uses staves of wood, deal as the cheapest, and coats them with any of his gutta-percha compositions, using one part of the composition to two of the solvent. When the solvent has thoroughly dried, he takes pieces of the required size and heats them, lays one upon the other, taking care to reverse the grain of the wood, and then presses the whole while hot, keeping the pressure upon them till cold.

The compositions he prefers for moulding without fabrics are—gutta-percha four parts, bone-charcoal two parts, and one-sixteenth part of arsenious acid; or, gutta-percha four parts, ground whalebone or the rasping of horns and hoofs two parts. If a hard composition of a light color is required, he uses gutta-percha three parts, ivory or bone-dust one part, and Cornish clay a half part. He states that a large quantity of animal charcoal or bone-dust will make these compositions much harder at the expense of their toughness. The articles he makes directly from these solid compositions are carriage and other wheels, ornamental leaves and scrolls for furniture, military and other ornaments for harness, trays, frames, cornices, leaves, and flowers. The quantity of perfumes to be used in any of these compositions must depend upon the purity of the material. He finds, however, that of orris root half a pound to every five pounds of the composition is necessary; of benzoin, two ounces to every five pounds; of the essential oils, about half an ounce to five pounds.

To finish the surfaces of fabrics or leather prepared with gutta-percha or its combinations, he coats them with transparent colors, made by combining the colors with oils or varnishes. His mode of operating is as follows:—Suppose the fabric is coated with gutta-percha, and animal charcoal or lamp-black, the color would be a dull black; to improve upon this, he takes

ten pounds of linseed oil and twenty ounces of Prussian blue, grinds and mixes, boils the whole gently until it is as thick as treacle, which is readily seen by trying a drop on a bit of glass, and when cold it will be found to be a brown transparent varnish. Apply a thin coat to the surface of the cloth, it will be dry in a few hours, and in drying will absorb oxygen and become blue, thus giving the cloth the fine color of black enamelled leather.

If other colors are required—as red, for example—the fabric should be coated with gutta-percha and vermilion. Take one pound of any oil-varnish, or pale linseed, nut, or poppy oil, previously made *drying* by any of the ordinary methods, and three ounces of crimson lake; grind them well together, and coat the fabric with a thin layer. If the fabric has been embossed or corked to imitate morocco leather, the result will not be a bad imitation of that article. Of course, any tinge may be produced by a similar process.

In July, 1848, Mr. ANTHONY LORIMER obtained a patent for improvements in the means of purifying gutta-percha, and for new combinations of that substance with other materials. The first part of the method claimed consists in a somewhat intricate system of knives and other machinery for slicing and kneading the gutta-percha; the second consists in combining it with burned clay, burned flint, broken articles of porcelain and earthenware, marble, Portland, Cornish, and other stones, all crushed and sifted; also, the oxides of zinc and copper, the hydrate and oxalate of lime; also a compound of lime slacked with oxalic acid dissolved in water. He uses about three pounds of acid to a bushel of lime, the acid being first dissolved in a quantity of water suitable for slacking that proportion of lime. For making soles for boots and shoes, the great object is to incorporate as much of either of the above matters, or mixtures thereof, as the gutta-percha will take up, and retain a flexible and adhesive character; but in cases where the compounds are to be subjected to strain, such as straps and bands, then smaller quantities of these substances must be combined with the gutta-percha. The gutta-percha compounds so produced may be moulded into any desired form, or pressed into sheets between rollers.

In November, 1854, a patent was taken by HENRI JULES DUVIVIER and HENRI CHAUDET of Paris, for a method of treating gutta-percha with the chloride, bromide, iodide, or fluoride of sulphur, or with the corresponding compounds of phosphorus, boron, silicon, and arsenic, or the bichlorides of tin and antimony; but of these substances the patentees prefer to employ the chloride of sulphur, although they allege that results similar to those obtained by the use of that compound may be obtained by the use of any of the other compounds above-mentioned. The process which they adopt for applying these substances is merely a modification of that vulcanizing process originally patented by Mr. PARKES. The gutta-percha is dissolved in bisulphide of carbon, the solution being made in a close vessel, and at a temperature of 86°. This menstruum, when purified by deposition, is evaporated to dryness, and another clear solution is made, to which from two to fifteen per cent. or more of chloride of sulphur,

diluted with bisulphide of carbon, is added and well mixed; or if any of the other substances before mentioned are employed in place of chloride of sulphur, then from fifteen to fifty per cent. should be employed. The patentees make the following interesting statements with reference to the properties of the resulting compounds, according to the proportions in which the ingredients are mixed:—

1. By mixing only two per cent. of chloride of sulphur, or only fifteen per cent. of the other substances, with the sirupy solution of gutta-percha, a compound is obtained which does not materially differ from gutta-percha in its properties.

2. When more than two per cent. of chloride of sulphur is employed, the compound can be extended when heated to 100° or 120°, and it remains extended when cooled, but retakes its original form when again heated; and at about 212° it agglutinates.

3. When five per cent. of chloride of sulphur is added, the compound only differs from that just described in being less softened by heat, and in being slightly elastic when cold.

4. When ten per cent. of chloride of sulphur is added, the properties of the gutta-percha are quite changed, and the compound is unaltered by a temperature of 212°.

5. When above fifteen per cent. of chloride of sulphur is added, the compound becomes horny and harder as the quantity of chloride of sulphur increases.

Articles may be formed from these compounds by pouring them as soon as mixed into metal or other suitable moulds, and there allowing them to set. In the same way the patentees cast blocks of elastic gutta-percha, which are afterwards cut up into pieces of a suitable size for rubbing out pencil marks. The compounds may also be used for glueing or attaching one substance to another, in which case they should be applied in a fluid state, and the two surfaces to be attached should be held together until the cement is quite hard. When attaching leather by this cement, the surface of the leather should be made rough. Or the process may be varied by first coating the surfaces to be attached with untransformed gutta-percha, and then wetting the surfaces with a solution of two to ten parts of chloride of sulphur in one hundred parts of bisulphide of carbon, and pressing the surfaces together till hard.

In a similar manner, articles may be coated with transformed gutta-percha, by dipping them first into a sirupy solution of gutta-percha in bisulphide of carbon, and afterwards plunging them into a bath consisting of two to ten parts of chloride of sulphur dissolved in one hundred parts of bichloride of carbon.

When it is desired that the gutta-percha should penetrate, in place of remaining as a coating on the surface of the article, as is sometimes desirable when treating sheets of fabric, wood, leather, and similar materials; then, in place of simply dipping the article in the solution of gutta-percha, it is allowed to soak therein for twenty-four to thirty-six hours, and is moderately heated, passed between rollers, and afterwards dipped into a solution of ten parts of chloride of sulphur in one hundred parts of bisulphide of carbon.

If the articles subjected to these processes are of such a nature that they would be damaged by the acid vapors formed during the operation, the patentees state that carbonate of soda should be mixed with the solution of gutta-percha, in quantity sufficient to neutralize the acid formed.

In June, 1855, a patent was taken by P. AUGUSTIN GODEFROY for mixing cocoa-nut shells in a finely-ground or comminuted state with gutta-percha in the process of its manufacture, by which it is alleged that the following advantages are obtained:—1. Considerable economy in the manufacture; 2. Greater durability in the product, especially when applied to the manufacture of boot-soles, clogs, goloshes, and other articles exposed to much wear; and 3. Greater elasticity, with the power of resisting a higher temperature than ordinary gutta-percha. By grinding machinery fitted for the purpose, the patentee reduces the cocoa-nut shells to powder of three degrees of fineness. The first, or finest quality, he employs for mixing with gutta-percha intended for tubing, for an insulating coating to telegraph wires, and such like purposes; the second or coarser, for driving-bands, boot-soles, ornamental mouldings, *et cetera*; the third, or coarsest quality, for lining ships, for hut linings, for covering floors and walls, and other similar purposes. The Editor can see no objection to a little adulteration of the gutta-percha for the latter two modes of its application; perhaps the admixture of cocoa-nut shell might even, in some respects, increase its adaptation for these and other purposes; but he doubts how far the same admixture would improve the quality of gutta-percha as an insulator of electricity, or as an admixture in the composition of tubes intended to resist acids, and to be impermeable to moisture.

A communicated patent, dated November 27, 1855, was taken for improvements in the manufacture of india-rubber and gutta-percha, by mixing with these materials calcined shells, or other cheap substances of a like nature, so that when afterwards vulcanized and rendered hard by being subjected to a high degree of heat, the material may be applicable to the manufacture of bobbins, cylinders, rollers, racks, ratchet-wheels, and other parts of spinning machines. Though gutta-percha is embraced in the patent, india-rubber seems to be the substance to which the admixture of calcined shells is considered most applicable.

In August, 1856, a patent was taken by Mr. CHARLES GOODYEAR for an improvement in combining gutta-percha with asphalte or pitch. The method previously in use was, to combine gutta-percha and asphalte by masticating the two together, in the same manner as gutta-percha and india-rubber are combined in the kneading machine. Mr. GOODYEAR's improvement consists in effecting the combination by the aid of hot water, by which the two matters are softened, and made comparatively fluid. For this purpose a close vessel is used, into which the substances are introduced, mixed with a quantity of water, and the temperature is raised to such a degree as to melt both; after which they are to be well stirred, to blend them together. He considers that this melting of them together effects the most perfect combination. And having been thus

thoroughly blended in a fluid state, they may, when desired, be further combined with sulphur, also with india-rubber and other matters; and the various compounds thus produced are, when required, subjected to high temperatures, in order to produce the change which is known as *vulcanizing*.

WATERPROOFING AND DEODORIZING.—Mr. HANCOCK's patent of January, 1846, embraced a method of producing varnishes which might be applied to the waterproofing of leather or cloths; and by applying them either alone or mixed with coloring matters to gutta-percha or its compounds, or to articles made from them, they might have a fine glossy exterior given to them, and the smell of any ingredients which might have been mixed up with them, such as that of the sulphur in vulcanizing, would be effectually removed. For this purpose he mixed gutta-percha and caoutchouc, or gutta-percha and jintawan—using the substances indifferently, so far as regards the proportion one bears to the other—with sulphur or orpiment, or other sulphide, in the proportions that are usually employed for vulcanizing, with about eight to ten parts of animal or vegetal wax, or animal or vegetal fatty matter, and then dissolved in rectified spirits of turpentine, and evaporated. He adds that these varnishes, mixed with colors, may be used for the purpose of painting or printing cloth, leather, or any other fabric, and will be found very useful as waterproof cements, particularly in combining gutta-percha and its compounds with silk, cotton, and other textile fabrics.

In November, 1853, a patent was taken by Mr. JOSEPH FRY for improvements in preparing solvents for india-rubber and gutta-percha, and in rendering waterproof fabrics free from smell. With reference to the first claim, it is stated in the specification, that previously the solvents employed for india-rubber and gutta-percha had been distilled and rectified before their application; but it had been found by the patentee that these solvents are improved if india-rubber or gutta-percha be combined with the solvents before distilling them, or be present in a certain proportion during that operation. The solvents usually employed for waterproofing purposes are turpentine and coal-naphtha, or coal-oil. In proceeding to distil one or other of these, he introduced into the still, along with the solvent, from four to six ounces of the india-rubber or gutta-percha to each gallon of the liquid; and he affirms that the product distilled over is materially improved for the purpose of its subsequent use in dissolving larger quantities of the same substances, while the residue in the still will be found useful for fabricating common or inferior articles, and for waterproofing coarser and lower-class cloths. Or, by another method, the crude solvent might be first distilled without india-rubber or gutta-percha being present, and afterwards be combined with india-rubber or gutta-percha, and again distilled or rectified. The latter mode of treatment is regarded by the patentee as producing the best result.

The second part of the claim, which has for its object the removal of the odor of articles fabricated of india-rubber or gutta-percha in which solvents have been used, consists in subjecting the waterproof cloths, whether before or after being made up into garments or

other articles, to the action of steam in a close chamber or steam-chest; and for this purpose the patentee does not find it necessary to employ steam of a much higher pressure than that of the atmosphere. A longer or shorter time is required to remove the odor of the solvent, according to the amount of it that has been present.

DECOLORING GUTTA-PERCHA.—In February, 1853, a patent was taken by Dr. NORMANDY for decoloring gutta-percha by means of animal charcoal, embracing also a novel method of forming it into sheets and balloons. The gutta-percha to be operated upon by this process is previously purified as much as possible by cutting, and pressing or kneading it in hot water. It is then exposed at a gentle heat to the action of some volatile solvent, such as essence of turpentine or benzol, but preferably of bisulphide of carbon, in which latter case no heat should be applied. One part by weight of gutta-percha dissolved in about twenty parts of solvent, yields a brown, turbid, sirupy mass, which is clarified and partly decolorized by first allowing it to stand till the heaviest particles subside. The supernatant liquid, still much colored, is thoroughly purified by filtration through animal charcoal; it is then put into a still provided with a refrigerator, and if it be desired to obtain the gutta-percha in a solid state, the distillation is continued to dryness. But to obtain sheets, or to make balloons, shades, and various other forms of gutta-percha, the patentee proceeds as follows:—He takes the purified solution of gutta-percha in bisulphide of carbon, and pours a certain quantity of it into a vessel—for example, a glass cylinder stopped at one end. He then inclines the vessel, and turns it in every direction, until its sides are completely and evenly coated over internally by the solution, and then allows the excess of liquid to drain off, by holding the glass cylinder with its mouth downwards. In a short time the bisulphide of carbon volatilizes completely, leaving the inside of the glass covered with a film or thin lining of gutta-percha, which loosens by its contraction in drying, and may then be readily extracted. Care must be taken, however, not to touch the cylinder with a warm hand, for the gutta-percha will adhere to the glass at the points which have been thus warmed. If the part which was in contact with the bottom, or closed part of the cylinder, be now cut off, a cylinder of gutta-percha, open at both ends, is obtained, and this being cut longitudinally, will form a sheet. Thin semi-transparent balloons, or almost any other form, may be produced in the same way, since the solution of gutta-percha will necessarily take the form of the vessel into which it is poured. When, however, the gutta-percha membrane has to be removed through a small aperture—which happens when the sirupy liquid has been poured into a bottle, or glass balloon, or mattress—some contrivance must be resorted to, as that of introducing into the vessel a tube, by means of which the air in the vessel can be sucked out, either by the mouth, or with a syringe; the gutta-percha membrane will thus be made to collapse and recede from the sides of the vessel, after which it may be easily removed. It is evident that the more viscid the solution, the thicker will be the membrane obtained.

DYEING OF GUTTA-PERCHA, AND ITS COMBINATIONS.—A method of coloring articles formed of gutta-percha, or coated with a varnish of that substance, has been just stated, in connection with Mr. HANCOCK's method of waterproofing and deodorizing. It is obvious that the same varnish which excludes moisture, and confines the odor of the solvent, may be mixed with colors, and will thus form a pigment of any required tint. This process may be termed painting, or color-varnishing; but in Mr. PARKES' patent for March, 1846, was embraced a claim for *dyeing* caoutchouc or gutta-percha, alone or in combination, and afterwards, when desired, treating those matters by vulcanizing agents, either in solution, or by the dry method. To dye caoutchouc, or gutta-percha, or their compounds, he boils them from a quarter to half an hour in the following preparations:—

Black.—One pound of sulphate of copper dissolved in one gallon of water, with one pound of caustic ammonia, or chloride of ammonium. Or—one pound of sulphate or bisulphate of potassa, and half a pound of sulphate of copper, with one gallon of water.

Green.—One pound of chloride of ammonium, half a pound of sulphate of copper, two pounds of caustic lime, and one gallon of water.

Purplish.—One pound of sulphate or bisulphate of potassa, one quarter of a pound of sulphate of copper, and one quarter of a pound of sulphate of indigo. Of course, the depth of color may be varied by varying the proportions of the ingredients.

Or the following colors may be applied directly:—

Blue.—Victoria blue and ultramarine.

Red.—Vermilion, carmine, or rose-lake.

Green.—Brunswick green, or acetate of copper.

Yellow.—Chrome yellow, or oxide of uranium.

White.—The color known as satin white. Mr. PARKES prefers generally to use this as a ground for the hues above-mentioned. *The coloring processes must precede the vulcanizing of the material.*

METALLIZING.—In Mr. HANCOCK's patent of February, 1847, was embraced a method of improving the quality of gutta-percha, both in its natural and vulcanized state, by exposing it for a minute or two to the action of binoxide of nitrogen, obtained by the usual method of dissolving a metal, such as zinc, copper, or mercury, in nitric acid, or by immersing it in a boiling and concentrated solution of chloride of zinc, for a period varying from one to five minutes, according to the strength of the solution. In either case, the materials are afterwards well washed in some alkaline solution, or in soft water. Gutta-percha which has been thus treated, and whether vulcanized or not, is stated by the patentee to become exceedingly smooth to the touch, and of a lustre approaching to metallic.

SUBSTITUTES FOR GUTTA-PERCHA.—In December, 1853, a patent was granted to STANISLAS T. M. SOREL, of Paris and London, for certain improved compositions to be employed as substitutes for caoutchouc and gutta-percha. These compositions, though termed substitutes, are simply combinations of gutta-percha with other bodies, resembling in most cases those already mentioned as patented by other individuals for the same purpose. This will be at once seen from the following

ingredients and proportions employed for his principal mixture:—

	Parts by weight.
Colophony,.....	2
Pitch or bitumen,	2
Resin oil,	8
Hydrated lime,	6
Water,.....	3
Pipe-clay, or other like argillaceous earths,	10
Gutta-percha,	12
	43

The patentee prepares the composition in a copper, heated by any suitable means. He first introduces into the vessel colophony, bitumen, or pitch, and resin oil, and agitates the mixture with a stick, or spatula, until the former two are dissolved. He then adds slacked and broken hydrate of lime of the consistence of molasses, continuing to agitate and heat the mixture, and when the latter is completely liquefied he introduces the gutta-percha, cut into small pieces. The agitation is continued till the gutta-percha is dissolved, when argil is introduced, either powdered or mixed with water, and well incorporated with the mixture. An excess of water is then added, and the whole is heated to ebullition. The matter is now separated and kneaded in water, then withdrawn from the copper and again heated, and passed several times between the rollers of a rolling machine to render it homogeneous, when it is ready to be employed.

The colophony may be replaced by other resins, as burgundy pitch, or gum-copal. The argillaceous earth may be entirely suppressed in the composition. To render the latter more tenacious, he increases the quantity of gutta-percha; and to augment still more its tenacity, and render it a little elastic, he adds a small quantity of natural or vulcanized caoutchouc, cut up, like the gutta-percha, into small pieces. To render the composition more completely waterproof, he adds about five per cent. of bees' wax or stearic acid. It may be colored with smoke-black, or other coloring matters.

Subjoined are three combinations, in the first of which the colophony is replaced by pitch; in the second, both the resin and resin oil are superseded; and in the third, pitch is replaced by coal-tar from the gas-works:—

	I.	II.	III.
Pitch,.....	8	12	—
Resin oil,	4	—	—
Coal tar,.....	—	—	12
Slacked hydrate of lime,	6	6	6
Gutta-percha,	16	16	16
	34	34	34

Argil may be added to the above three compositions. They are stated by the patentee to be applicable for replacing caoutchouc and gutta-percha in their principal applications, and especially for waterproofing stuffs, and the manufacture of tubing, of driving-straps, waterproof boots and shoes, bobbins and cylinders for spinning machinery, capsules for stopping bottles, and other like articles. They may likewise be moulded for making vases, and other ornamental articles. For giving the composition greater tenacity, fibrous materials, such as cotton, wool, hemp, cow hair, and leather

waste, may be added. When properly rolled into sheets, it may be lined or covered with thin sheets of natural or vulcanized caoutchouc by means of a rolling machine, or by sticking them together with a solution of caoutchouc or gutta-percha, or any other suitable adhesive agent. These double sheets may be employed for the upper leathers of waterproof boots and shoes. The soles may be either of waterproofed leather, of gutta-percha, or of wood.

ADULTERATIONS.—From the list of patents which have been given for mixing or combining gutta-percha with other substances, including caoutchouc, pitch, pipe-clay, vegetal wax, calcined bones, coal-tar, lime, sulphur, cocoa-nut shell, Portland stone, and an almost infinite variety of other materials, all of which are assumed by the respective patentees to peculiarly adapt the resulting compound for certain specified applications, it may seem unreasonable to brand as adulterations the admixture of ingredients which are added by legal sanction for certain avowed purposes. On this extreme principle even the process of vulcanizing, which imparts to caoutchouc and gutta-percha more than half their value, would be a sophistication; for it presupposes the admixture of the article with sulphur, or some of its compounds. Allowing, therefore, that gutta-percha may be too often adulterated, and deteriorated for all practical uses, under patent authority, while, on the other hand, the fact is undeniable that by certain admixtures and combinations the qualities of the compound are improved for certain purposes, the Editor will confine himself to those adulterations which are practised by the native Malays and Chinese traders, and in consequence of which an impure or inferior article is palmed on the European importer.

The fact that the native Malays often introduce stones, earth, and other impurities, into the blocks of gutta, to increase their weight, has been already noticed, and may also be left out of consideration, as these impurities are often too easily detected, to the injury of the machinery of the manufacturer. Such impurities are also readily eliminated in the process of purification. But the case is otherwise, when, as frequently happens, the gutta-percha is mixed with other gums of an inferior character. The chief trade in the article is carried on by the Chinese, who adulterate it with the valueless juice of a tree called *Getah Malabeöya*, which they import from Palembang. By this admixture various sorts of gutta-percha are obtained, which differ considerably in price. Among several samples examined by M. ADRIANI, one was in cakes of five to six inches thick, and was darker on the outside than in the interior; another was of a very loose structure, and was much contaminated with small stones, but agreed in color, which was in general a flesh-red, with the former; a third sample was white, slightly inclined to brown. This last piece had been removed as an impurity from a large block of gutta-percha, but was found to be in quality perfectly equal to the best gutta, and was afterwards rolled out in the manufactory of MUNNICH, BECKE, and Co., into sheets of the thickness of paper, for address cards for that firm. The same chemist obtained a sample of

the *Getah Malabeöya*, imported from Palembang, and also a sample of gutta-percha adulterated with that substance. The getah, which seemed to be also an inspissated milky juice, was imported in the form of plates, of about an inch in thickness, of a greyish color, somewhat clammy to the touch, and brittle when dried. When cut, it was found of a dirty white color, and contained many impurities. Like gutta-percha, it was dissolved by chloroform. The vessel in which it was contained emitted, on being opened, a disagreeable acid smell. Treated like gutta-percha, and purified by hot water, it was much darker than the raw substance, and often quite black; the smell was equally offensive, and its consistency similar to that of wax or glaziers' putty. The gutta-percha adulterated with the getah was of a loose texture, of a more greyish color, and of a smell different from that of genuine gutta. In warm water the getah became soft and sticky; treated with boiling water, it formed a neutral milky liquid, which was precipitated by alcohol. When boiled with alcohol it became glutinous, the alcohol extracting a white fat, resembling wax and resin; ether extracted also resin. Being dissolved in chloroform and filtered, a black coloring substance remained behind, which could not be dissolved by the usual solvents, and was burnt without leaving a residue. It appeared to be nothing else but soot. The getah melts at 170°, and becomes decomposed only at a much higher temperature, when dark-colored oils are distilled off.

USES AND APPLICATIONS.—From several processes described in connection with the manufacture of gutta-percha, and from the list of patents enumerated under the head of its combinations, *et cetera*, the reader will have seen that the substance admits of a vast variety of applications; and, indeed, the mere consideration of its singular and valuable properties is sufficient to show that the only bar to its almost indefinite extension into the arts and uses of life is the considerable price of the article, arising from its necessarily limited supply compared with the great demand for it. Its chemical and other properties have been already stated, but in now proceeding to give a more extended list of its applications, it may not be out of place to remark that these will be found chiefly to depend on the following peculiarities:—

1. Its capacity of being moulded by gentle heat and pressure into any required form, and of retaining this impressed form when cold, with extreme tenacity.
2. Its pliability at common temperatures.
3. Its impermeability to water and other fluids.
4. Its power of resisting not only the solvent action of common liquids, but even the corrosive action of most acids, of caustic alkalies, and alcoholic liquors.
5. Its valuable property as an insulator or non-conductor of electricity, in which respect it ranks second to no other known substance.
6. Its singular acoustic properties, as a conductor of sound.
7. Its capacity of combining with sulphur or its compounds, and being vulcanized like caoutchouc, so as to be unaffected by considerable changes of temperature.
8. Its aptitude for uniting with various other substances in any required proportion, so as to produce

compounds combining remarkable hardness with a certain amount of elasticity.

9. Its power of receiving and retaining the sharpest and finest impressions from the die or mould.

10. Its great durability at common temperatures, and under almost all agencies.

To these properties, separately or conjointly, may be traced its peculiar fitness for the following applications, namely: For a protection to underground and submarine telegraph-wires—a purpose for which it is not less fitted by its pliancy and its resistance to moisture than by its high insulating power; for replacing the cylinder or disc of electrical machines; for insulating handles and other electrical apparatus; for tubes to convey not only cold water, but acids, alkalies, and other corrosive liquids; for bath-cisterns, buckets, bottles, or other vessels; for lining acid and alkali cisterns formed of wood; baths for photographic purposes, and different laboratory apparatus; sieves and pumps for acid and alkaline liquors; funnels, siphons, valves, and stop-cocks for corrosive solutions; conversation tubes for mines, ships, warehouses, or railways; stethoscopes and other surgical instruments; driving-bands for all kinds of machinery; rollers, bobbins, *et cetera*; boot and shoe-soles—one of its most extensive applications; waterproof clogs for dyers or maltmen; horse-trappings; waterproof cases for charts, maps, arms, and such like; noiseless rings for bed and window curtains; cords for window-sashes and blinds; clothes-lines; whips; waterproof portmanteaus; hats for miners, sailors, carriers, *et cetera*; moulded objects of every description, as fancy baskets, bread-trays, ink-stands, watch-stands, clock-cases, medals, picture-frames, buttons, flower-pots, and various similar applications.

The author of the Jury Report on the manufactures from gutta-percha in the Great Exhibition, says:—It is especially in the fabrication of articles for maritime use that gutta-percha—resisting, as it does, the action of water, and especially of brine—appears to be the best adapted. Buoys of every description for anchors, nets, *et cetera*, have been made of it; sailors' hats, speaking trumpets, and the like. It may be added that even fish-nets are formed of gutta-percha cord. It will be seen from the preceding enumeration of uses, that the decorative art has also taken large advantage of the plastic properties of gutta-percha. Various articles of furniture, the prices of which are so much enhanced by carving, are capable of being reproduced by means of pressure, and thus multiplied at a comparatively low price. Writing-tables, work-baskets, *et cetera*, can be produced in gutta-percha, and thus made to combine the threefold advantage of lowness of price, elegance of form, and absence of fragility. In the London Gutta-Percha Company's Works are made every day a great quantity of mouldings, friezes, panels, leaves, and articles of every description. These, combined by the decorator, and covered with gilding, which gutta-percha takes in perfection, are, in the manufacture of picture-frames, and in the decoration of furniture, capable of superseding the carving upon wood, which is so costly, or papier-maché and carton-pierre, which present the defect of great fragility.

Bronze articles have also been reproduced in a fel-

icitous manner. At the Great Exhibition, the West Ham Gutta-Percha Company, represented by Mr. HANCOCK, exhibited, among various other objects, a beautiful group representing a boar-hunt, covered with a metallic coating in imitation of bronze. The author of the Jury Report remarks, that the clearness of the edges and the purity of the forms which gutta-percha receives in the mould, make it easy to understand how this substance has been found capable of being used for making galvano-plastic moulds, and how some experiments have been tried for the purpose of substituting gutta-percha in the process of stereotyping, for the metal with which at the present day the pages of illustrated books are multiplied. Stereotype plates of gutta-percha, with specimen impressions, were actually exhibited by the London Gutta-Percha Company, in connection with a large unfinished machine, intended for printing therewith on endless paper, which was also to be cut and folded before leaving the machine, the gutta-percha types not requiring the paper to be damped. It does not appear, however, that this application of gutta-percha has been brought into general use. Moulded into the form of a jawbone, it has been found capable of holding together artificial teeth, and thus advantageously superseding those settings in gold which were so costly, and which, on account of their absolute rigidity, presented much inconvenience. The solution of gutta-percha in oil of tar and other solvents, which, by their evaporation, leave the gutta uninjured, can be made use of to obtain sheets of extreme thinness, which have begun to be extensively used in surgery. But, apart from its use as a covering for submarine telegraph wires, and its common application as a substitute for leather soles, it is more especially to the manufacture of tubes and chemical utensils for the conveyance and conservation of acids, *et cetera*, that gutta-percha seems calculated to render the greatest services.

STATISTICS.—The imports of gutta-percha into the United Kingdom in 1850, amounted to one thousand two hundred and fifty tons. The prices vary, according to the supply and demand, from fourpence to one shilling and fourpence per pound—average, eightpence—showing the aggregate value of the above imports to be equivalent to ninety-two thousand five hundred and fifty pounds sterling. The article is manufactured in London, Manchester, and Liverpool.

HYDROCYANIC ACID.—*Acide prussique*, French; *Berlinerblausäure*, *Hydrocyansäure*, German; *Acidum hydrocyanicum* vel *Borussicum*, Latin.—This important compound—which, from its animal origin, has also been named *zootic acid*, and the poisonous properties of which are, unfortunately, so well known—was first isolated by SCHEELE. DIESBACH and DIPPEL, in 1704, discovered Prussian blue. Forty-eight years afterwards, MACQUER found that lime-water resolved this substance into *calc of iron*—sesquioxide—and a *combustible coloring matter*, which he could not separate, but which combined with potassa, forming *phlogisticated potassa*—ferrocyanide of potassium. GUYTON MORVEAU concluded in 1772 that this principle had acid properties. In the year 1782, SCHEELE succeeded in preparing the aqueous solution of *prussic acid*, which

he said was composed of ammonia, acid of air, and phlogiston. BERTHOLLET, in 1787, described it, in similar terms, as consisting of carbon, hydrogen, and nitrogen. PROUST and ITTNER discovered several of its compounds, and the latter is said to have procured anhydrous hydrocyanic acid by the action of hydrochloric acid upon cyanide of mercury, but, being unable to condense the vapor, he pronounced it to be a permanent gas. GAY-LUSSAC, however, in 1811, effected its liquefaction, determined the relative proportions of its ultimate elements, and led the way to the intimate knowledge and useful application of many of its compounds.

SOURCES AND PREPARATION.—Hydrocyanic acid exists, ready-formed, in many vegetal substances; and is generated in many others, in which it was formerly believed to pre-exist, by the various methods which were devised for its extraction. The kernels of bitter almonds, plums, peaches, apricots, and cherries, the leaves and more tender branches of the peach, the leaves of the Portugal and cherry laurel, and many portions of other vegetables belonging to the sub-orders *Pomeæ* and *Amygdaleæ*, when steeped in water for a considerable time and then distilled, yield hydrocyanic acid. According to several authorities, amongst whom are LIEBIG and WÖHLER, the formation of the hydrocyanic acid during the immersion of the vegetal substances in water, is caused by the action of the *emulsin* upon the *amygdalin*—both of which they contain—as a ferment, decomposing the latter into grape-sugar, bitter almond oil, and hydrocyanic acid—the latter two passing over in the subsequent distillation.

It is now generally received that it is only in the more moist of such vegetal structures that the acid is ready-formed. There have been adverse opinions with regard to its presence in the leaves of the cherry laurel; GUIBOURT and LEPAGE maintaining that it is formed during their immersion, while WINCKLER holds that bitter almond oil containing hydrocyanic acid does really exist in the fresh leaves in minute quantity, which he believes varies with the amount of water present, disappearing entirely when the leaves are exsiccated.

Hydrocyanic acid is produced in many ways. According to FOWNES, when nitrogen gas is passed over a mixture of equal parts of pure sugar, charcoal, and carbonate of potassa in a porcelain tube at a red heat, carbonic oxide, and subsequently nitrogen, pass off; cyanide of potassium and a carbonaceous mass remaining. When ERDMANN and MARCHAND repeated this process with pure materials, and at a moderate red heat, no cyanide was formed; and even when the temperature was raised to such a degree that vapors of potassium were carried off with the carbonic oxide, they could discern doubtful traces only: on employing carbonate of potassa containing sulphate, the presence of sulphocyanide of the alkali was evident. WÖHLER states that the production of cyanide of potassium from sugar-charcoal, carbonate of potassa, and nitrogen, is indubitably ascertained, but it is required that the nitrogen should be at a red heat, and that the temperature of the tube and its contents should be such that potassium is volatilized.

DESFOSES has observed, that when nitrogen gas is

passed through a mixture of *wood-charcoal* and carbonate of potassa, heated to redness, a small quantity of cyanide is generated; but as wood contains albuminous matter, and its charcoal is not entirely free from it, the nitrogen might either wholly or in part emanate thence.

GMELIN, citing the experiments of RIEKEN,—in which carbonate of potassa mixed with charcoal obtained from the purest white sugar, and heated in a current of nitrogen gas, at a temperature sufficiently high to reduce potassium, was completely converted into cyanide of the alkali-metal; in one case so effectually that the cyanide did not even effervesce with acids—and taking into consideration the fact, that when a mixture of potassium or antimonide of potassium with charcoal is heated to full redness in a current of nitrogen, not a trace of cyanide of potassium can be detected,—concludes that this formation of cyanogen requires not only the presence of free potassium, but at the same time a temperature high enough to separate potassium from its oxide.

When blood, hoofs, horns, and many animal tissues are ignited with carbonate of potassa; when blood, fats, sugar, gum, starch, and many organic bodies, both nitrogenous and free from that element, are subjected to distillation with nitric acid; and in many other instances, and by other means, is hydrocyanic acid produced. PEREIRA mentions the statement that cheese, when exposed to the action of water and the sun, disengages ammonia, and when treated in this state with alcohol, yields traces of hydrocyanic acid.

Examples of the formation of hydrocyanic acid having been given, it now remains to pass on to its preparation. Many methods having this object in view have been devised; some intended to produce the acid anhydrous, others, in a dilute state. The former modes will first be noticed, commencing with that of GAY-LUSSAC, which is as under:—

Into a perfectly clean tubulated glass retort, introduce a quantity of finely-powdered cyanide of mercury, and then add rather less than the same weight of hydrochloric acid, having a specific gravity of about 1.2. Next adapt to the beak of the retort, in a horizontal position, a glass tube, about half an inch in diameter, and two feet in length. One third of this, at the end next the retort, is filled with pieces of marble, for the purpose of retaining any hydrochloric acid which may pass off with the hydrocyanic acid. To the remainder of the tube fragments of fused chloride of calcium are supplied, which absorb the aqueous vapor. To the outer extremity of this purification tube is adapted a small receiver, surrounded with a freezing mixture. The hydrocyanic acid is expelled by means of heat; but it is advisable not to raise this very high, as, in that case, too much hydrochloric acid might be evolved, and not only is this a source of inconvenience, but, by the disengagement of much carbonic acid from the marble, hydrocyanic acid may be carried off. The use of too large a quantity of hydrochloric acid is, for the same reason, to be avoided. The reaction in this case is thus represented:—

By VAUQUELIN's process the cyanide of mercury is carefully placed in a long glass tube, terminating, at one extremity, in a small receiver surrounded by a freezing mixture, and having attached to the other end a proper apparatus for the supply of pure dry sulphide of hydrogen; this gas, on passing over the metallic cyanide, liberates its acid, and unites with the mercury to form sulphide; thus:—

The whole of the cyanide of mercury may be decomposed by gently heating the tube, while the gas is still passing through it; but it is better to leave a little of the metallic cyanide undecomposed, the product of the operation being thus preserved from contamination with the sulphide of hydrogen.

The last mode of procedure which it will be requisite to describe here is that of TRAUTWEIN. Fifteen parts of finely-powdered ferrocyanide of potassium are distilled at a gentle heat with nine parts of sulphuric acid, previously diluted with an equal weight of water; the distillate is collected in a well-cooled receiver, containing five parts of pure chloride of calcium, broken into small pieces. When the hydrocyanic acid has accumulated in sufficient quantity to cover the chloride of calcium, it is poured off into a well-stoppered glass vessel. The cyanide of potassium of the ferrocyanide is decomposed as in the former two processes; thus:—

For medical purposes, hydrocyanic acid is always employed in a dilute state, and as the means for directly obtaining this are preferable and more certain than that of letting down the anhydrous acid with water, many have been devised. The London College directs that seven drachms of sulphuric acid be mixed with four fluid ounces of water, and when cooled put into a retort; next two ounces of ferrocyanide of potassium are dissolved in ten ounces of water, and added. Eight fluid ounces of water are then placed in a cooled receiver, and heat being applied to the retort, six fluid ounces of acid are distilled over. Lastly, to this dilute acid are added six more fluid ounces of water, or so much that one hundred grains of the acid are entirely thrown down by 12·59 grains of nitrate of silver. Hence, it contains two, or, more exactly, 1·92 per cent. of real hydrocyanic acid.

The dilute acid of the Edinburgh College contains, according to SQUIRE, 3·98, or, according to Dr. CHRISTISON, 3·3 per cent. of anhydrous acid. The Dublin College has not fixed the strength of the acid prescribed in its Pharmacopœia. SQUIRE represents it to contain rather more than two per cent. of dry acid.

EVERETT, in 1835, proposed an entirely different plan for at once preparing the dilute acid. Dr. PEREIRA characterises it as yielding an acid of uniform strength, and as being available when the acid is required for immediate use. It consists in decomposing forty grains of cyanide of silver, with forty minims of dilute hydro-

chloric acid—specific gravity 1·129—made up to a fluid ounce with water.

Dr. CLARKE has suggested another process:—

Eight and a quarter parts of cyanide of potassium are dissolved in one hundred of water, and to this solution is added another of eighteen and a half drachms of crystallized tartaric acid in twenty of water. Bitartrate of potassa is thus precipitated, while the supernatant fluid contains about 2·8 per cent. of hydrocyanic acid, together with traces of bitartrate of potassa held in solution.

Again, a known quantity of cyanide of mercury is dissolved in water, and a stream of sulphide of hydrogen passed through the menstruum, which is then removed from the metallic sulphide by filtration. VAUQUELIN directs that the excess of sulphide of hydrogen should be thrown down from the solution by means of carbonate of lead. According to BRANDE, it is difficult to obtain a clear and colorless solution by this process without the addition of a drop or two of hydrochloric acid.

COMPOSITION.—It has already been stated in the introductory portion of the present article, that BERTHOLLET ascertained that the ultimate elements of hydrocyanic acid were carbon, hydrogen, and nitrogen. GAY-LUSSAC, in 1825, verified this, and, succeeding in obtaining the acid in an anhydrous state, determined the relative proportions of its constituents, with the following results:—

	At. weight.	Centesimally.
2 Eqs. Carbon,	12	44·45
1 Eq. Hydrogen,	1	3·70
1 Eq. Nitrogen,	14	51·85
1 Eq. Hydrocyanic acid, ...	27	100·00
Symbol:—C ₂ H N = H Cy.		

PROPERTIES.—At ordinary temperatures, anhydrous hydrocyanic acid is a clear, limpid fluid, possessing a strong penetrating odor—similar to that evolved when bitter almonds are bruised—and an acid, somewhat bitter taste. It faintly reddens blue litmus paper, but the tinge disappears as the acid evaporates in the air. It is so volatile, that when a drop is placed upon a glass plate, it freezes by the rapidity of its own evaporation. With water or alcohol it unites in any degree. Its specific gravity at 45° is 0·705, and at 64° 0·696. It boils at 79° or 80°. It congeals at 5° into a fibrous mass, having a great resemblance to crystallized nitrate of ammonia. SCHULTZ states that the perfectly anhydrous acid is still fluid under 0°, and that the solidification at 5° is owing to the presence of water.

Hydrocyanic acid is decomposed with facility under the influence of light, ammonia being generated, and a brown substance, not hitherto examined, deposited; this transformation is prevented by the presence of a small quantity of a mineral acid. Concentrated sulphuric, nitric, and hydrochloric acids decompose it, when water is present, into formic acid and oxide of ammonium, the elements of which it contains:—

According to PELOUZE and GEIGER, the same decomposition of hydrocyanic acid into formic acid and ammonia is produced by the action of the fixed alkalies at elevated temperatures, probably in consequence of the predisposing affinity of the latter for formic acid:—

LIEBIG has found that when hydrocyanic acid is mixed with sulphide of ammonium, and the liquid heated till its color is destroyed, sulphocyanide of ammonium is formed, and this, giving immediately a blood-red hue with salts of sesquioxide of iron, forms the basis of a most delicate test for the acid, which is said to be distinctly recognizable, even when only the three thousand nine hundred and thirtieth part of a grain is present in the solution.

With nitrate of silver, hydrocyanic acid gives a precipitate, soluble, on boiling, in nitric acid; when with potassa, then a mixture of a proto- and sesqui-salt of iron, and, subsequently, an excess of hydrochloric acid are added to it, whether it is in the dilute or anhydrous state, Prussian blue is formed.

Both the anhydrous acid and its vapor are readily combustible, burning with a ruddy flame. The vapor, according to GAY-LUSSAC, has a density of 0.9476; when mixed with oxygen, it may be exploded by the electric spark, each volume of the former requiring for perfect combustion five of the latter. The products of this metamorphosis are—two volumes of carbonic acid, one of nitrogen, and one of water:—

The vapor mixed with hydrogen is, according to GAY-LUSSAC, but imperfectly decomposed by a succession of electric sparks, the gaseous compound depositing a small quantity of charcoal, and perceptibly increasing in volume. GMELIN remarks, that this expansion is not very easy to account for, unless it be due to the formation of carbonic oxide, or hydrogen arising from the presence of water.

Potassium heated in the vapor of the acid unites with the cyanogen and liberates hydrogen.

According to GAY-LUSSAC, hydrocyanic acid and hydrogen slowly produce, with oxide of copper, gaseous cyanogen and water, subcyanide of the metal probably being formed:—

The same authority asserts, that binoxide of manganese will absorb a mixture of hydrocyanic vapor with hydrogen gas, without separation of cyanogen.

PHYSIOLOGICAL EFFECTS, *et cetera*.—Although any notice, however brief, of the physiological effects of hydrocyanic acid may appear to be irrelevant here, as

belonging more properly to medicine, yet the Editor conceives that, without alluding to it, the article would not be complete, and it may have its uses. For most of the information on the subject he is indebted to Dr. PEREIRA.

Hydrocyanic acid is poisonous to the vegetal as well as to the animal kingdom. When the stems of plants, possessing irritability, are immersed in the acid, they lose this property. It prevents the milk of lactescent plants from leaving its cells, and deprives seeds of their germinating power.

Experiments have been made on animals generally, from the *mammalia* down to the *infusoria*, with hydrocyanic acid. The effects appear to have been similar in nearly every instance, the animals being convulsed, and losing sensation and voluntary motion.

According to GRAY, however, some larvæ of the *musca* remained uninjured after two or three days' immersion in the acid.

Rabbits, dogs, *et cetera*, are deprived of life by it in a few seconds, whether it is administered to them internally in the fluid form, or inhaled in the state of vapor. Even when a drop is placed on the throat or eye of a dog, death occurs in a very few moments.

It was first introduced into medicine about the year 1806 by the Italian practitioners, BORDA, BRUGNATELLI, and RASORI. Its use in England was much furthered by the investigations of Drs. A. T. THOMSON and ELLIOTSON in 1820 and the subsequent year. It has been tried as a remedial agent in many affections of the pulmonary organs, in derangements of the nervous system, in hydrophobia, as an anodyne, and as an anthelmintic, with questionable success; and it is now employed only for alleviating disorders of the stomach. The dose of course varies with the kind of acid employed. Of the acid prepared according to the London Pharmacopœia, two to seven minims may be administered. One to four minims of the acid of the Edinburgh College, or one to five minims of the Dublin preparation, are accounted a dose.

When given in medicinal doses, cautiously increased, the following effects may, according to Dr. PEREIRA, be observed:—A bitter, but peculiar taste; increased secretion of saliva; irritation in the throat; frequently nausea; disordered and laborious respiration, sometimes quick, at others slow and deep; pain in the head, giddiness, obscured vision, and sleepiness. In some instances faintness is experienced.

When administered in poisonous doses of moderate quantity, a remarkably bitter taste is experienced immediately after swallowing the acid; this is soon followed by a sensation of faintness and giddiness, with salivation, and is succeeded by tetanic convulsions and insensibility; the respiration is difficult and spasmodic; the odor of the acid may be recognized in the breath; the pupils are usually dilated, though sometimes contracted; the pulse is small and imperceptible. When recovery takes place it is usually very rapid, and the whole period of suffering seldom exceeds half an hour, though there have been exceptions, in which the symptoms have extended over several hours.

When hydrocyanic acid is taken into the human system in immoderate quantity, death supervenes so

speedily that the symptoms have scarcely been observed. They are probably similar to those noticed in animals, *videlicet*, imperceptible pulse, breathing not obvious; or there may be two or three deep, hurried inspirations, insensibility, and death. Convulsions may or may not be present.

The great variation in the strength of the acid renders uncertain three points of inquiry, each in itself interesting; namely, the quantity required to produce death, the time at which it begins to operate, and the period at which it proves fatal. Peculiarities not known or understood also affect the result. Very strong acid, in large doses, begins to operate very speedily, especially if its vapor be inhaled. The diluted acid, on the other hand, sometimes does not produce any obvious effect for several minutes, and death may not occur for nearly half an hour.—*Pereira*.

The mode in which hydrocyanic acid acts on the human frame is not without interest. Dr. CHRISTISON cites the case of ROBQUET, whose fingers were benumbed several days in consequence of their being exposed to the vapor of the acid. Hence it appears that the acid acts locally on the nerves. From the odor of the acid being exhaled from animals poisoned by it, and from the detection of it by KRIMER in the blood, it is clear that the poison is absorbed; but physiologists differ as to whether the remote effects produced by it are due to absorption. Dr. PEREIRA sums up the arguments which have been adduced in favor of this theory, as follow:—

Firstly: The acid produces no remote effects when applied either to the nerves or brain. Secondly: When applied to the tongue or stomach, it acts as an energetic poison, although the nerves of these parts were previously divided. Thirdly: That if the acid be applied to a part where circulation is arrested, the operation of the poison is prevented. Fourthly: The activity of the acid is in proportion to the absorbing powers of the part with which it is placed in contact. Fifthly: A sufficient time always elapses between its application to the body and the first symptom of its action, to admit of its operation by absorption.

The principal antidotes in cases of poisoning by hydrocyanic acid are chlorine, ammonia, cold affusion, and respiration by artificial means. Though the latter should on no account be omitted, yet the first two are universally admitted to be the most efficacious. Chlorine is given in various forms, as in very dilute aqueous solution, of which one or two teaspoonfuls may be administered at intervals. Or a weak solution of chloroxide of calcium—bleaching powder—or of chloroxide of sodium may be substituted for chlorine water. Chlorine gas largely diluted with common air may be carefully inspired by the patient. Ammonia is employed in the ordinary fluid state, largely emasculated; but much has been said in favor of the inhalation of the vapor of ammonia or its carbonate, as the preferable way of employing the volatile alkali.

ADULTERATION.—It cannot be positively affirmed that hydrocyanic acid is intentionally adulterated, though there is considerable reason to believe that it is often sold in too dilute a state. But, amongst all the methods for its preparation, there are none by

which it can be prepared absolutely pure without the use of the utmost precautions in every stage of the process. Hence, when due care is wanting, deteriorating substances often find their way from the retort to the receiver in considerable quantity. Again, however careful may have been its production, it is liable to decomposition if not properly preserved; this is especially the case when, from recklessness in its preparation, it contains foreign principles; for these, by their action on one another, on the acid itself, or from spontaneous decomposition, may give rise to a multiplicity of products, till ultimately the acid has completely disappeared, and there remains instead an *olla podrida* worthless to the owner, and which, if administered as a remedial agent, might be productive of the worst consequences.

Pure hydrocyanic acid is entirely volatilized by heat. Should a residue be left when it is carefully evaporated, it may consist of bitartrate of potassa, oxide of lead, cyanide of mercury, or of other substances according to the mode by which it is produced. Thus, the acid made by CLARKE's method often contains a portion of the first-named salt; while that prepared according to the directions of VAUQUELIN may be contaminated with the latter substances.

The stronger acids, as sulphuric or hydrochloric, are frequently present. In this case, litmus paper is strongly and permanently reddened; and when a mixture of cyanide of mercury with iodide of potassium—formed by commingling the concentrated solutions of these salts, when the double compound falls in white crystalline plates—is added to the suspected acid, the beautiful red iodide of mercury is deposited. This test occasions no change if the hydrocyanic acid be pure.

Sulphuric acid may be detected by the addition of chloride of barium, which occasions a white precipitate, insoluble in nitric or hydrochloric acid.

Nitrate of silver causes a precipitate of cyanide of silver; and should hydrochloric acid be present, of chloride of silver. The former—cyanide—is dissolved on the addition of boiling concentrated nitric acid, while the latter remains as a white curdy deposit.

Hydrocyanic acid containing ammonia soon acquires a brown color. When treated with a strong solution of potassa in the cold, ammonia is evolved, and may be recognized by the smell, and by the white vapors which are observable when a glass stirrer moistened with hydrochloric acid is placed in immediate contiguity with it.

The acid prepared by VAUQUELIN's process frequently contains lead. This may be detected by passing a stream of sulphide of hydrogen through the acid; if lead is present in large quantity, a brownish-black deposit is speedily formed; when the amount is small, a brownish coloration only is occasioned. Sulphuric acid will likewise throw down a white precipitate of sulphate of lead.

VAUQUELIN's acid may also hold cyanide of mercury in solution, if the current of sulphide of hydrogen were not long enough continued in its preparation. It is detected by saturating the acid with this gas, when the brown sulphide of mercury is formed.

When the hydrocyanic acid has been prepared, by

distilling a metallic cyanide with sulphuric or hydrochloric acid, formic acid may be retained in solution. This acid reddens litmus more strongly and permanently than does the pure hydrocyanic acid. On dissolving suboxide of mercury in the acid, and heating the menstruum, the mercury is reduced, producing a grey cloudiness, from which, when deposited, globules of metallic mercury may be elicited by friction. According to GEIGER, if the greater part of the fluid be gently evaporated, the residue reduces suboxide of mercury with effervescence.

Should hydrosulphocyanic acid be present in hydrocyanic acid, it may immediately be discovered, by adding a salt of sesquioxide of iron, when a fine blood-red color, more or less deep, appears.

DETECTION AND DETERMINATION.—The detection of hydrocyanic acid is oftentimes of the greatest importance, especially in cases of poisoning. Of late years, chemistry has, in this respect, given evidence most important and incontrovertible.

In many instances, hydrocyanic acid may be recognized by its odor, even when in a dilute state, when surrounded by decaying organic matter, or when itself partially decomposed. According to ORFILA, this test is the most delicate one, since, he says, it gives very marked indications when those afforded by the liquid reagents are only slight. This statement, however, must be received carefully, as much is necessarily dependent on the nature of the mixture containing or supposed to contain the acid.

The reaction of caustic potassa, proto- and sesquioxide of iron, and hydrochloric acid, upon a fluid containing hydrocyanic acid, is a valuable means of detecting the latter. The mixture under examination is saturated with caustic potassa, and a solution of a proto- and sesquisalt of iron is added. The precipitate thus formed may vary in color, according to the quantity of potassa or of the salts of iron present; sometimes being yellowish, at others blue, and again, partaking of both hues, being green. Whatever be the tint, it is immediately changed to that of Prussian blue, on the addition of a little hydrochloric acid. Care must be taken not to employ too much potassa, which would prevent the development of the Prussian blue.

Nitrate of silver also indicates with great delicacy the presence of hydrocyanic acid, causing a white flocculent precipitate, soluble in *boiling* concentrated nitric acid. The latter property distinguishes it from the chloride of silver, which it much resembles. Should further proof be required that the deposited compound is the cyanide, it may be carefully dried, introduced into a glass tube, and heated in the flame of a spirit lamp. Cyanogen gas is evolved, and this is readily combustible, burning with a purplish flame.

The discovery of LIEBIG, that when hydrocyanic acid was mixed with sulphide of ammonium, and subjected to a moderate degree of heat, a compound—sulphocyanide of ammonium—was formed, which possessed the property of giving an intense blood-red color with the sesquisalts of iron, afforded a test for hydrocyanic acid, which is equal, if not superior, to any at present known. Dr. PEREIRA remarks:—When the acid is in small quantity, and mixed with solids or

fluids, partially decomposed, then a modification of this test will enable one to detect a quantity of the poison which, from its minuteness, and from the absence of the usual odor, might otherwise escape notice. This slightly varied method is as follows:—Introduce the poisoned liquid or solid into a beaker or other similar vessel, which it should fill to within half an inch of the brim. Place upon a large watch-glass, which fits with tolerable accuracy to the beaker, two or three drops of sulphide of ammonium, containing an excess of sulphur, and invert it over the liquid. In three or four minutes, the watch-glass may be removed, and the moistened spot dried, with care and very gently, over a spirit-lamp or sand-bath. A white film remains, which may be either sulphur—resulting from the evaporation of the sulphide of ammonium—or sulphocyanide of ammonium, formed by the action of hydrocyanic acid, in the suspected liquid, upon the sulphide of the volatile alkali. In the latter case, the film will have a crystalline character, which, if not visible to the unassisted eye, may be detected by means of a microscope. Further, the film, if of sulphur merely, is not affected when moistened with water, and treated with a drop of sesquichloride of iron; whereas, when it consists of sulphocyanide of ammonium, the ferruginous sesquisalt immediately occasions a blood-red color, which is discharged upon the addition of a few drops of a solution of chloride of mercury. Should the film upon the watch-glass have a yellowish color, it is probably sulphide of ammonium, in which case the iron salt will give a black precipitate of sulphide of iron, thus showing that the evaporation has not been sufficient.

It should be observed, that both the Prussian blue and the nitrate of silver tests should be applied, when the suspected substance, as in cases of poisoning, contains foreign matters upon a distillate. Thus, if the contents of a stomach are under examination, they are introduced into a tubulated retort, and one-half distilled by means of a vapor or water-bath. Should the substance be alkaline—soon known by applying red litmus paper, which is at once colored blue—it may be owing to the generation of ammonia by putrefactive decomposition, and it is advisable to introduce a few drops of sulphuric acid into the retort along with the matters to be distilled.

It has been suggested that hydrocyanic acid may be formed during the distillation of organic matters. Dr. CHRISTISON rightly remarks that this objection appears only to rest on conjecture or presumption. The Editor would advise in all cases of importance, that the sulphur test, as modified by Dr. PEREIRA, and given above, should be first resorted to, and then the other tests may be proceeded with upon the original substance or a distillate from it, as its nature may render advisable, without risk of error.

The determination of hydrocyanic acid, which now presents itself to notice, is often of considerable importance, but never more so than when it is required to know the strength of an acid for medicinal purposes. Formerly, the density and the strength of the acid were supposed to be proportional, and Dr. URE constructed a table of specific gravities and corresponding strengths; but it has since appeared that these are

fallacious. He subsequently proposed the following method:—Weigh out a portion of the hydrocyanic acid, and add, by degrees, a known quantity of red oxide of mercury, agitating the menstruum after each addition, till it is no longer dissolved, and the odor of the acid has disappeared. By weighing the remaining oxide, the quantity employed is known, and since one hundred and eight parts of oxide require twenty-seven of anhydrous hydrocyanic acid for its liquefaction, the proportion of the latter is readily calculated. But DUFLOS has shown that the cyanide of mercury first formed is capable of taking up more oxide, even at ordinary temperatures, so that this method gives too much acid, especially if the liquid is not kept quite cool, and the addition of oxide stopped as soon as the odor of hydrocyanic acid has disappeared. Care, too, must be taken that the acid is perfectly free from hydrochloric acid, which also dissolves the protoxide of mercury. In this case, GEOGHEGAN neutralizes the hydrochloric acid with carbonate of lime before adding the oxide.

The last-mentioned chemist has directed, for the estimation of prussic acid, that nitrate of silver mixed with a small quantity of ammonia—so that the liquid after precipitation may be rather acid than alkaline—should be dropped into a known quantity of the acid, as long as a precipitate is produced. This is collected on a previously dried and tared filter, welledulcorated, dried at 212°, and weighed. One hundred and thirty-five parts of cyanide of mercury represent twenty-seven of the anhydrous acid.

Perhaps the most elegant mode of determining hydrocyanic acid is that last suggested by LIEBIG, and based upon the property of cyanide of potassium of dissolving chloride of silver, so as to produce a double cyanide containing an equivalent each of the cyanides of silver and potassium. The hydrocyanic acid is supersaturated with potassa, and mixed with a few drops of a solution of chloride of sodium; nitrate of silver is then added, until a permanent precipitate is produced. The proportion of the silver in the dissolved nitrate being known, the amount of hydrocyanic acid is readily calculated, since it is in the exact proportion of two equivalents to one of the silver consumed: thus supposing eighty-five grains of nitrate to have been used, which are equivalent to fifty-four of the metal, half the latter number—twenty-seven—will be the number of grains of anhydrous hydrocyanic acid present in the weighed portion operated upon. This nice method is also applicable for the estimation of the acid in cherry-laurel water, *et cetera*.

INK.—*Encre*, French; *Tinte*, German; *Atramentum*, Latin.—Ink, according to the purposes for which it is intended, is found in different forms. Writing ink, which is of various colors, is liquid, and may be either a clear fluid, as ordinary red ink, or may consist of a finely-divided precipitate equally diffused through the menstruum, as in common black ink. Printing ink is likewise of divers hues, but has a pasty consistence. The form of ink known as *Indian*, which is employed more especially as a water-color, is in solid cakes.

The present subject will be treated of in the following order:—

1. Writing inks, which are either *colored*, as black, red, blue, green, and violet; or *sympathetic*—that is, those which are colorless when committed to paper, as also when dried, but, by the application of heat, moisture, or of some compound which may be said to act as a mordant, they become visible, and are then either permanent or fugitive; in the latter case, the tint being generally caused to reappear by again applying the suitable means.

Besides these may be noticed the lithographic *transfer* inks, some kinds of which are used with the pen, and must consequently be included under this first class.

2. *Printing Inks.*—These, in all their numerous diversities of color and consistence, will be considered with reference to the purposes to which they are applied, as for letterpress, lithographic, and copperplate printing.

WRITING INKS.—There are few chemical preparations, perhaps none, of which the benefit in civilized life is so great, or of which the use is so widely extended, as that of common writing ink; consequently, there is no compound the quality of which it is so necessary to inquire into; and yet there is perhaps no subject which, up to a comparatively recent period, has been more neglected by chemists.

Before LEWIS, towards the close of the last century, directed his attention to the subject, no author appears to have particularly applied himself to inquire into the theory of the composition of ink, or to bring it to perfection. All that is to be found in the works of previous writers, consists merely of formulæ for various kinds of ink, which, being composed without any attention to chemical laws, were more or less defective; so that it may be truly said, that until the time of LEWIS, the preparation of writing fluids, the properties of which it is so essential to attend to, was left entirely to chance, or to empirical prescriptions.

It is indeed true, that some good kinds of ink have been discovered by accident; but those who devised them kept their composition secret, so that the public were either obliged to purchase those inks from the inventors, or to make use of such as were inferior in quality, and more or less perishable.

Ordinary black writing ink is now made from galls, sulphate of iron, green copperas, and gum. Other substances may be and often are employed, but those just named are the only requisite, and the best materials.

The ancient inks, according to the opinions of most writers, were similar to the Indian or Chinese ink of the present day. PLINY and VITRUVIUS allude to it as a combination of soot or lamp-black, with glue or gum; DIOSCORIDES even mentions the proportions of three of the former to one of the latter. To these, according to some authors, the liquor extracted from the cuttle-fish was added. When this could not be obtained, or from other causes, it is evident that some of the modern sulphurized ingredients were added by the ancients; many Greek and Roman manuscripts erased by the monks having been found to retain as much of the vitriolic principle as to become again legible on the application of chemical tests.—*Encyclopædia Britannica*.

Still, very little really definite knowledge of ancient writing inks can be obtained, and the Editor will therefore confine his attention to the modern ones.

Dr. LEWIS, already mentioned, found that equal weights of galls and sulphate of iron gave an ink, which, although of a good color when used, subsequently became yellowish-brown; that as the quantity of sulphate was increased, the inks were less durable in color, and that those in which the galls predominated, were most persistent. The proportions which he deemed best were:—

Powdered sulphate of iron,.....	1 ounce.
Ground logwood,.....	1 “
Bruised galls,.....	3 “
Gum-arabic,.....	1 “
White wine, or acetic acid,.....	1 quart.

He found that, although water answered for all ordinary purposes, white wine gave a deeper-colored product, and the ink made with acetic acid was still blacker. Alcohol was injurious to the hue, causing a deposition of the tinctorial precipitate. A decoction of logwood, substituted for water, improved the black both in richness and depth of tint. He directs the materials to be put into a glass, earthenware, or other non-metallic vessel, and the mixture agitated four or five times every day. In ten or twelve days it is ready for use—if placed in a warm situation, considerably earlier; but if the ink is allowed to remain on the matériel, it continues to improve for a lengthened period. When decanted, it may be kept in good order with greater certainty, if a few broken—not bruised—galls, and two or three fragments of iron, are placed in it.

LEWIS preferred distilled or rain water in making ink, but spring water containing calcareous salts is better adapted for the purpose. Some remarks on this subject, extracted from NAPIER, have been inserted in the article DYEING.—See Vol. I., page 584.

RIBAUCOURT, who devoted much attention to the manufacture of inks, and published an extended paper in the *Annales de Chimie*, in the year 1798, observes:—None of the ingredients of ink should be in excess. If there be a deficiency of galls, a portion of the sulphate of iron will not be decomposed; if, on the contrary, the galls are in excess, the ferrous sulphate will take as much as it can decompose, but the remainder will be nearly in the state of decoction of galls, subject to change by becoming mouldy, or undergoing a transmutation after the ink has been used, destroying the legibility of the writing much more completely than would be the case were the sulphate of iron present in too large quantity. He further considers it doubtful whether the principles of galls are extracted by mere maceration, and says that inks thus made always flow pale from the pen, and are never of so deep a black as those in the manufacture of which the galls have been subjected to a long-continued boiling. The following recipe was devised by RIBAUCOURT, as affording a good writing fluid:—

Boil eight ounces of coarsely-pulverized Aleppo galls and four ounces of thin logwood chips in twelve pounds of water for one hour, or until half the liquid is evaporated. Pass the decoction through a hair-sieve or

linen cloth, and then add four ounces of sulphate of iron, three ounces of gum-arabic, one ounce of sulphate of copper, and one ounce of sugar-candy. Agitate the mixture till the whole is dissolved, and leave it at rest for twenty-four hours; then decant the ink, and preserve it in well-stopped stoneware or glass bottles.

In making good writing ink, remarks Professor BRANDE, the great object is to regulate the proportion of sulphate of iron to the galls. If the former be in excess, although the ink may at first appear black, it becomes subsequently brown and yellow. Hence, some time should elapse before ink is used, after the ingredients are put together, in order to be tested from time to time, and the combinations perfectly regulated. The gum is added to retain the coloring matter in suspension, to prevent too great fluidity in the writing, and to protect the organic matter from decomposition.

If the paper has been made from inferior rags, bleached by an excess of chlorine, ink deposited upon it, however good, will be ultimately discolored. An excellent product is obtained as follows:—

Boil six ounces of finely-bruised Aleppo galls in six pints of water; then add four ounces of clean and well crystallized sulphate of iron, and four ounces of gum-arabic. Keep the whole in a wooden or glass vessel, occasionally shaken. In two months, strain, and pour off the ink into glass bottles.—*Brande*.

Dr. URE directs that twelve pounds of bruised galls be put into a cylindrical copper, of a depth equal to its diameter, and boiled, during three hours, with nine gallons of water, taking care to replace at intervals what may be dissipated by evaporation. The decoction is then to be emptied into a tub, allowed to settle, and the superstratum of liquid having been drawn off, the marc is to be drained. Some recommend the addition of a little bullock's blood or white of egg, to remove a portion of the tannin; but this abstraction, says URE, tends to lessen the product, and will seldom be practised by the manufacturer intent upon a large return for his capital. Five pounds of gum-senegal are next dissolved in a small quantity of hot water, and the mucilage thus formed, being filtered, is added to the clear decoction. Five pounds of sulphate of iron are now dissolved in as small a quantity of water as possible, and added. The color darkens by degrees, in consequence of the oxidation of the iron, on exposing the ink to the action of the air; when a moderately deep tint has been obtained, it should be drawn off clear into bottles, and well corked up. Dr. URE prefers digesting, rather than boiling, the galls.

The following prescription is given in the seventh volume of the *Pharmaceutical Journal*:—

Galls, bruised,.....	2 pounds.
Sulphate of iron,.....	5 “
Gum-arabic,.....	4 “
Water,.....	12 gallons.
Creosote,.....	2 drachms.

Boil the galls in three-fourths of the water for an hour, then strain. Liquefy the gum in twice its weight of hot water, and add it to the decoction. Dissolve the copperas in the remainder of the water, mix the liquors together, and finally stir in the creosote. It is very evident that in this recipe there is a great deficiency of

galls; otherwise, the quantity of sulphate of iron should be considerably reduced. The creosote is added as a preventive of mould, for which it is most efficient. BOOTH gives the following formulæ:—For superior black ink, take twelve pounds Aleppo galls, four pounds sulphate of iron, three and a half pounds of gum, and eighteen gallons of water. For a fine exchequer ink, forty pounds of Aleppo galls, nine pounds of sulphate of iron, ten pounds of gum, and forty-five gallons of water. In both these cases, it is directed that the bruised galls be exhausted by three consecutive boilings, each time diminishing the quantity of water, and supplying, by fresh addition, any loss by evaporation. The copperas and gum in solution are added to the strained decoction of galls, whilst both are yet warm, and the whole is allowed to repose for several weeks, when the fluid is drawn off from the sediment. A few cloves, or some drops of creosote are added, to prevent any parasitic growth.

REID gave, in the *Philosophical Transactions* of 1827, among many valuable observations which will subsequently be noticed in this article, the following proportions:—

Galls, bruised,.....	1 pound.
Sulphate of iron,.....	3 ounces, 64 grains.
Gum,.....	3 ounces, 64 grains.
Water,.....	3 quarts.

The galls are to be boiled with three pints of water till a quart of decoction remains; it is then poured off, the remainder of the water added, and ebullition continued until again a quart only is left. The two menstrua are then mixed, and the other ingredients dissolved in them; the whole is allowed to rest for twenty-four hours, when the fluid ink is poured off, and retained for use.

By another method, REID makes the decoction of galls as above directed, and exposes it freely to the air for ten days, agitating it two or three times each day. By this means much of the tannin is converted into gallic acid. To each quart of the decoction, add three and a half pints of water, nine ounces of sulphate of iron, and the same quantity of gum. The deposit which forms may, after three days, be separated, when the ink is fit for use.

Again, one pound of galls is exhausted as first directed, and the tannin of the decoction changed, by exposure, into gallic acid, as in the last instance. The menstruum is then mixed with a saturated solution of logwood, freshly made by boiling a pound and a half of the chips in five quarts of water, till the quantity is reduced to seven pints; eighteen ounces of sulphate of iron, and as many of gum, are dissolved in this mixed liquid; the whole is allowed to stand for two or three days, and the ink is then decanted from the sediment.

An attempt was formerly made to prepare ink by macerating iron filings in an infusion of galls; but though the resulting liquid was of the required hue, the writing produced with it was totally devoid of permanency, and was readily washed from the paper.

Japan ink is made as other inks, but the sulphate of iron is oxidised by roasting. This ink is intensely black when written with, but the color does not retain its depth or lustre. Besides these disadvantages, it

clogs the pen, and is, altogether, far from being worthy of recommendation.

Before giving the formulæ for, or notices of, inks prepared from other than the ordinary ingredients, it may be well to introduce here some remarks from a paper presented by Dr. BOSTOCK, in the year 1830, to the Society of Arts, which, though containing perhaps a few slight inaccuracies, is indicative of no small amount of research; and embodying, as it does to a great extent, the Editor's views, he does not consider any apology for its length to be requisite. Dr. BOSTOCK says:—

When the sulphate of iron and the infusion of galls are mixed, for the purpose of forming ink, it may be presumed that the metallic oxide enters into combination with at least four proximate vegetal principles, which constitute the bulk of the soluble portion of galls, namely, gallic and tannic acids, mucilage, and extractive matter. Two of these, the gallic acid and tannin, are more especially necessary to the constitution of ink, which is considered by some of the best chemists to be essentially a tanno-gallate of iron. It is also laid down, that the sesquioxide of iron alone possesses the property of forming the compound which constitutes black ink, and that the substance of the latter is mechanically suspended, rather than dissolved in it.

Ink, as it is usually prepared, is disposed to undergo certain changes, which considerably impair its value; of these the three following are the most important:—its tendency to moulding; the liability of the black matter to separate from the fluid, the ink then becoming what is termed *ropy*; and its loss of color, the black first changing to brown, and at length almost entirely disappearing.

Besides these, there are objects of minor importance to be attended to in the formation of ink. Its consistence should be such that it will easily flow from the pen, without being so fluid as to blur the paper, or so adhesive as to clog the pen, and to be long in drying. The shade of color is not to be disregarded; a black, approaching to blue, is generally preferred to a browner ink; and a degree of lustre or glossiness, if compatible with the due spissitude of the fluid, tends to render the characters more legible and beautiful.

With respect to the chemical constitution of ink, Dr. BOSTOCK remarks that although, as usually prepared, it is a combination of the metallic salt or oxide with tannic and gallic acids, mucilage, and extractive matter; yet the last three of them, so far from being essential, are, without doubt, the principal cause of the difficulty which is encountered in the formation of a perfect and durable ink. He illustrated this point by a series of experiments. Having prepared an infusion of galls, a portion of it was exposed to the atmosphere in a shallow capsule, until it was covered with a thick stratum of mould; this being removed by filtration, and the proper proportion of sulphate of iron added to the clear fluid, a compound was formed of a deep black hue, which showed no further tendency to foul, and which remained for a long time without undergoing any further alteration.

Another portion of the same infusion of galls had a

solution of isinglass added to it, until a precipitate was no longer occasioned; by adding sulphate of iron to the filtered liquid, a black compound was produced, which, although paler than that made from the entire fluid, appeared to be a perfect and durable ink.

Lastly, a portion of the infusion of galls was subjected to continued ebullition, by which means part of its contents became insoluble; the menstruum was filtered, and sulphate of iron added to the filtrate, producing a good and permanent ink.

Dr. BOSTOCK presumes that the three causes of deterioration in writing fluids, the fungoid growth, the subsidence of the black compound, and the loss of color, are dependent upon the operation of different proximate principles: the first change he ascribes to the mucilage; the second to the extractive matter, from the property which it possesses of forming insoluble compounds with metallic oxides; the third he believes to be owing to the tannic acid, which probably, in the first instance, forms a triple compound with the gallic acid and the iron, and that, in consequence of the decomposition of the tannin, this body is subsequently destroyed. Owing to the difficulty, if not impossibility of depriving the infusion of galls of any one of its ingredients, without, in some degree, affecting the others, the last-named authority was unable to obtain any results which could be considered decisive; but experiments led him to conclude that, in proportion as ink consists merely of the gallate of iron, it is less liable to decomposition, or to experience any kind of metamorphosis.

Dr. BOSTOCK's summary is as follows:—In order to procure an ink which may be little disposed either to mould or to deposit its contents, and which, at the same time, may possess a deep black hue not liable to fade, the galls should be macerated for some hours in hot water, and the fluid filtered; the filtrate should be then exposed for about fourteen days to a warm atmosphere, when any fungoid growth that may be observed must be removed. A solution of sulphate of iron is to be employed which has been boiled, or exposed for some time to the air, and in which there is consequently an admixture of sesquioxide of iron. If the infusion of galls be made considerably stronger than is generally directed, the ink formed in this manner will not necessarily require the addition of a mucilaginous substance to render it of a proper consistence.

Dr. BOSTOCK adds further, in the *Transactions of the Society of Arts*, that one of the best fluids for diluting ink, if it be, in the first instance, too thick for use, or if it afterwards become so by evaporation, is a strong decoction of coffee, which does not appear to occasion the decomposition of the ink, while it improves its hue, and gives it an additional lustre.

The black color produced by galls in union with sulphate of iron, although faulty from its disposition to precipitate and decompose, was, from its being the only known method of making a black tinctorial solution, the sole article used during a very considerable period for atramental purposes. To those whose chief employment consisted in writing, copying, *et cetera*, the least defect in the ink caused a more or less serious addition to their labor, and the improvements made in

this fluid may, therefore, be considered as real and valuable benefits.

A semi-colored solution, such as were the old ferro-gallic inks, requiring the addition of gum to prevent the deposition of the tinctorial matter, was especially liable to thicken, and flow tardily from the pen: this in sultry weather, when evaporation is rapid, became especially irksome. The introduction of the steel pen made these imperfections more manifest, causing a greater liability in the ink to concrete and deposit its coloring matter.

Writing inks were in this state when the improvements introduced by Mr. HENRY STEPHENS of London first appeared. This gentleman, applying the knowledge of chemistry which he obtained in his studies for the medical profession, to which he once belonged, engaged in extensive and successful researches upon atramental fluids.

The first improvement introduced by him consisted of a blue liquid, which had the startling novelty of becoming intensely black in a few hours after its deposition on the paper. It had the great recommendation of perfect fluidity, and the ease with which it was transferred from pen to paper, coupled with its ready but tenacious combination with the latter, were, at that time, considered really remarkable. This now celebrated writing fluid is a tanno-gallate of iron dissolved in sulphate of indigo; the common ferro-gallic writing inks consist of a liquid in which the tinctorial matter is suspended by means of gum, while in this the color is in complete solution.

RUNGE, after endeavoring for a long time to find a black fluid possessing the properties of forming no deposit, of adhering strongly to the paper, of being unaffected by acids, and, lastly, of neither acting nor being acted upon by steel pens, succeeded after many experiments. The composition has the advantages of being very simple and exceedingly cheap. It is prepared by adding one part of chromate of potassa to one thousand parts of a saturated solution of logwood, made by boiling twenty-two pounds of logwood in a sufficient quantity of water to give fourteen gallons of decoction; to this menstruum, when cold, the chromate is gradually added, and the mixture well stirred. The addition of gum is injurious. In the preparation of this ink, it must be remembered that the chromate, not the bichromate, of potassa is employed, and great care is requisite to insure the due adjustment of the relative proportions of the ingredients used. The best way is to make the decoction of logwood, and *gradually* add to it, well stirring the mixture, as much solution of chromate as will give the desired shade.

It appears astonishing, says RUNGE, what a small quantity of chromate of potassa is required to convert a large amount of decoction of logwood into a black writing fluid; the fact is, however, certain, and care must be taken not to allow the proportion of chrome salt to exceed one part for one thousand parts of decoction of logwood, as a larger quantity exercises a prejudicial effect in destroying the tinctorial matter of the liquid, whilst, in the proportion above mentioned, a deep blue-black writing ink is formed, which, unlike the ink made with tanno-gallate of iron, is perfectly fluid, forming no deposit. This fluid possesses another advantage; the paper which has been written upon

with it may be washed with a sponge, or be left twenty-four hours under water, without the marks being erased. Weak acids do not destroy the writing, nor do they even change the shade, whilst that made from galls is effaced, and the ink made with logwood and sulphate of iron is turned red.

It is especially necessary, in using this atramental fluid, that the steel pens should be well cleansed from the greasy matter with which, when new, they are always coated. This may either be done in the usual way, by moistening them with saliva, and subsequently washing them with water; or, preferably, by applying to them an alkaline solution. RUNGE used this ink for two years without his steel pens being in the least affected, either by being crusted, or clogged with solid matter, or by becoming rusty.

Professor TRAILL has proposed a formula for ink as follows:—Gluten, obtained in the ordinary way, is kept from twenty-four to thirty-six hours in water, and is then digested in acetic acid having the specific gravity 1.033 or 1.034, in the proportion of three parts of gluten to twenty parts of the acid. By the aid of a gentle heat, a greyish-white, saponaceous fluid, which may be kept for some time, is obtained. From eight to twelve grains of the finest lamp-black, and two grains of indigo, form the coloring matter for each fluid ounce of the vehicle, with which it must be thoroughly incorporated. An agreeable aroma may be communicated by digesting bruised cloves, pimento, or cinnamon, in a portion of the original acid. This ink may be used with a steel pen, but should not be left in it, and the pen should be washed after use; it is not calculated for writing on parchment.—*Edinburgh Philosophical Transactions*.

Mr. HENRY STEPHENS has invented an indelible carbon ink, which, if at all equalled, is certainly not surpassed. His process is as follows:—

Take common carbonated alkali, or the potassa or soda of commerce, or ammonia, or some other alkaline compound, and mix it with resinous matter,—as shell-lac or common resin,—in about equal proportions; then add water according to the required strength of the solution, and boil the whole until the resinous substance, or the greater portion of it, has dissolved; next mix the necessary quantity of fine lamp-black with this solution. A black liquid will thus be produced, which may be mixed with other suitable colored solutions, to form an indelible ink. Such tinctorial matter as is soluble in alkali, will best assimilate with this composition.

A recipe for an indelible carbon ink, published in the year 1845, by HERBERGER, is perfectly identical with that of Dr. TRAILL just given.

Dr. NORMANDY has suggested an indelible writing ink, which cannot be obliterated or defaced by any known chemical agent. Twenty-four pounds of Frankfort black must be ground with mucilage—formed by adding twenty pounds of gum to sixty gallons of water—and the mixture strained through a coarse flannel, or passed through a funnel the tube of which is closed by a sponge; four pounds of oxalic acid are then added, together with as much decoction of cochineal and sulphate of indigo as will give the required shade.

Many substitutes for galls, in the manufacture of ink, have been suggested—principally for the sake of economy. Those of Dr. NORMANDY and M. GIROND are most worthy of notice. The former chemist employs sumach, elm wood, elder, chestnut, beech, willow, oak, plum, sycamore, cherry, poplar wood, catechu, or any other ligneous matter or berry, or extract of vegetal substances, containing gallic acid and tannin, or either of these principles. In making ink by this method, which is patented, the bark, wood, or berry, as the case may be, is reduced to powder, and boiled with water until a sufficiently strong decoction has been obtained. The quantity of water must vary, of course, according to the sort of vegetal substance employed; thus sumach will demand more water than catechu, on account of the latter being almost wholly soluble. To the menstruum is added a certain amount of logwood, of acetate and hydrate of protoxide of copper, of sulphate of alumina and potassa, and of sulphate of protoxide of iron, in quantities which must be regulated according to the nature of the organic matter first made use of. Gum-arabic or a superior quality of gum-senegal is now added, in the proportion of eighty pounds or thereabouts for each three hundred and forty gallons of liquid; also a variable amount of sulphate. As the quantity of the ingredients must be regulated by the shade of the tint intended to be produced, it is impossible to indicate absolutely the proportions in which they are to be employed; this must be decided by the taste and fancy of the manipulator. Supposing, however, that a blue-black is desired, and that sumach is the vegetal substance to which preference is given, the annexed are the proportions for two hundred and forty gallons of the ink:—Sumach, from forty-eight to sixty bushels; logwood, about two hundredweight—the quantity slightly varying, according as new or old chip is taken; gum-arabic, from eighty to one hundred and twelve pounds; protosulphate of iron, one hundredweight; acetate and hydrate of protoxide of copper, four pounds; sulphate of alumina and potassa, thirty-seven pounds; sulphate of indigo, six pounds or more, according to the required intensity of the blue. Were catechu to be employed in this case, instead of sumach, one hundredweight would be required, the proportions of the other materials remaining the same.

The obstacles which have hitherto prevented the use of the above-named astringent vegetal substances instead of galls, are the variously-colored precipitates which they afford with salts of iron, some being quite green, others brown, while decoction of galls yields with sulphate of iron a dark purple. These hues may, however, be altered at will, by the use of sulphate of indigo in different proportions, from dark-blue to the most intense black, applicable to dyeing, staining, or writing, and which may be employed with every description of pen.

The substitute for galls, patented by GIROND in 1825, is denominated by him, *damajavag*, and consists of an extract from the shell, wood, or sap of the chestnut tree.

One hundredweight of chestnut shells, broken into fragments, is to be immersed in from one hundred and

eighty to two hundred gallons of water, in a vessel of copper or other material *except iron*; and after having been allowed to soak for about twelve hours, heat is applied, and ebullition maintained for about twelve hours. If the wood of the chestnut tree is employed, it is cut into small pieces or thin shavings, and treated in the same way.

The extract is drawn off from the boiler at the end of the time specified, and filtered through a fine sieve or cloth, after which the water is evaporated from it until it becomes of a pasty consistence, when it may be cut into cakes of any convenient size, and dried in an oven at a low temperature till hard, at which time it is ready for use.

In making ink with this substitute, it is merely necessary to reduce it to a coarse powder, and use it as galls.

One hundredweight of chestnut shells yields eight or ten pounds of the dry extract.

SCOTT, in the year 1840, patented the following method for the manufacture of ink:—

Take forty-eight pounds of logwood chips, and let them be saturated two days in soft water; then boil them in a closely-covered iron caldron, with eighty gallons of the last-named liquid, for one hour and a half, when the wood must be taken out, and forty-eight pounds of the best Aleppo galls added to the menstruum, which must be boiled for half an hour, and subsequently allowed to remain in the vessel for twenty-four hours, during which time it must be frequently agitated. When the principles of the galls have been sufficiently extracted, draw off the clear fluid into a vat, and add forty pounds of pulverized sulphate of iron; let these ingredients remain for a week, during which time they should be daily agitated; then pour in four gallons of vinegar. Next take seven and a half pounds of the best picked gum-arabic, and dissolve it in sufficient water to form a good mucilage, which must be well strained, and then by degrees be mixed with the fluid; let these stand a few days longer, then add twenty ounces of concentrated nitrate of iron. When the menstruum has attained a sufficient depth of color, it is carefully decanted from the sediment, and the following substances, each separately prepared and ground, added to it:—

First, grind half a pound of Spanish indigo by means of a muller and stone, till it is very fine, occasionally adding portions of the ink until it is made into an easily soluble paste; then take five pounds of well-washed and purified Prussian blue, which must be prepared as the indigo, except that distilled water must be employed instead of the partially-prepared writing fluid. Next take four ounces of *gas-black*,—that is, the carbon collected from the smoke of gas-burners on glass surfaces—and grind it with one ounce of the nitrate of iron. These several substances are allowed to remain for a few hours unmixed, when the whole may be incorporated with the fluid, which is daily agitated for a week. The clear ink, in quantity about eighty gallons, is then poured off for use.

The Rev. J. B. READE of Aylesbury took out patents in the year 1847 for various writing, marking, and printing inks. The first only will be here noticed; the second and third will be described in their proper

places in the subsequent part of the article. The only black writing ink which he has devised, is made by mixing soluble Prussian blue of a good quality—prepared by Mr. READE's own patent, and described in the manufacture of his blue ink—with ordinary gall ink. This addition of Prussian blue makes the ink, which was already unaffected by alkalies, equally proof against acids, and a writing fluid is thus obtained which cannot, according to the patentee, be erased from paper by any common method of obliteration without destroying the tissue.

Two or three black inks now remain to be noticed, which, from the nature of the ingredients, can hardly be classed with the common varieties, and have, on that account, been reserved for description to the last. The first, and not the least important, of these is BERZELIUS' indelible ink, prepared from the metal vanadium. Vanadic acid, when combined with ammonia, thus forming a vanadate of the volatile alkali, and mixed with an infusion of galls, forms a black fluid, which, according to the inventor, is the best writing ink that can be used. The quantity of salt necessary for a perfectly black ink is so small, that, to use the great chemist's own expression, it will not be worth considering when vanadium is more generally known. The writing obtained with this ink is perfectly black. Acids do not obliterate it, though they cause the color to become blue. Alkalies, when diluted so as not to act upon the paper, do not dissolve it. Chlorine, though it destroys the black color, does not efface the writing, even when water is suffered to run over it. Though this ink cannot be said to be absolutely indelible, yet it strongly resists reagents which cause common ink to disappear. It has also the advantage of being a solution, and not merely a precipitate suspended in a fluid by means of gum, so that it flows more freely from the pen.

COATHUPE has given a formula for an ink capable of resisting the action of all the substances usually employed for effacing writing. It is prepared as follows:—Boil, in a loosely-covered tin vessel, two ounces of shell-lac and one ounce of borax with eighteen ounces of distilled or rain water, stirring them occasionally until the whole is perfectly homogeneous; filter the mixture, when cold, through bibulous paper, and mix the filtrate—in quantity about nineteen ounces—with one ounce of mucilage of gum-arabic, made by dissolving the gum in double its weight of water, and add pulverized indigo and lamp-black *ad libitum*. Seethe the whole again in a covered vessel, and agitate the menstruum thoroughly in order to effect the complete solution of the gum and the admixture of the coloring matters. This agitation is continued during the cooling of the fluid, after which it is allowed to repose for a few hours, so as to permit the deposition of the excess of indigo and carbon, when it is decanted and bottled for use.

An *indelible safety ink*, patented by WHITFIELD in 1837, is prepared in the following manner:—Four gallons of linseed oil; two of cocoa-nut oil; one gallon of good molasses; five pounds of loaf sugar; two pounds each of ground sacre seed, ground cotton seed, Venice turpentine, ivory black, Antwerp black, finely-powdered

burnt horns, tartar, pulverized gum-kino, and anacardium nuts; four pounds each of very finely-powdered charcoal, dried bullocks' blood, and gum-arabic; one pound each of solution of caoutchouc, parchment-shavings, powdered seed-lac, and Indian borax; and three pounds each of Aleppo galls, pomegranate peel, fine glue, and walnut skins, all in fine powder,—are mixed and boiled in a large iron caldron. On the commencement of ebullition, the mixture is ignited with a bar of red-hot iron, and the smoke which is liberated is received into a capacious inverted cone made of the best sheet-iron. As soon as the whole of the oil is consumed, the carbon which adheres to the cone is collected and carefully preserved. The residuum is then removed from the boiler, and rubbed down on a stone slab to an impalpable powder. One pound of the carbon collected in the cone, and a similar quantity of the prepared residuum, are then mixed with a quart of the best French vinegar, two gallons of hot water, and four ounces of gum-lac, and these ingredients are then boiled for ten minutes, when one pound of Aleppo galls in fine powder, and two pounds of logwood chips are added. The mixture is stirred until cold, and is then poured into large flat pans, and exposed to the atmosphere for three weeks.

Whatever may be the qualities of this ink when manufactured, it is certainly prepared in a singular manner. A mere tyro in chemical science will at once perceive that the materials are selected and proportioned so as to form a rare *olla podrida*, while the subsequent treatment of them is, to say the very least of it, wasteful in the extreme.

Copying inks, or inks which, after having been transferred from pen to paper, and having become dry, will communicate a portion of their substance to a sheet of damped paper strongly compressed upon them, thus furnishing two, and, in some instances—by renewed application, with pressure, of clean moistened paper—even a third or fourth copy of the same manuscript, are generally prepared by adding a modicum of sugar or sugar-candy, with an increased amount of gum, to the ordinary ferro-gallic inks.

RED INK.—The red inks at present in common use are of two kinds, of which, however, there are some modifications.

The first variety is prepared by making a solution of the tinctorial matter of Brazil-wood in acetic acid, the color being *raised* by means of alum.

BOOTH gives the following formula for a red ink:—Brazil-wood, two ounces; chloride of tin, half a drachm; gum-arabic, one drachm; water, thirty-two ounces. These ingredients are subjected to continuous ebullition, until the quantity of fluid amounts to only sixteen ounces.

HEUSLER's recipe is here given:—Boil two ounces of Brazil-wood, half an ounce of pulverized alum, and the same quantity of crystals of bitartrate of potassa in sixteen ounces of distilled water, until the fluid is reduced to one-half. Strain the liquor, dissolve in it half an ounce of gum-arabic, then mix with it a tincture made by digesting a drachm and a half of cochineal in one and a half ounce of alcohol of specific gravity 0.839.

Red inks of the second class are prepared from cochineal or carmin; the most common modification is a simple solution of the latter in an excess of ammonia, the proportions being varied according to the depth of color required. Such ink is extremely fugitive.

The following recipe is given in the *Pharmaceutical Journal*:—Place in a porcelain vessel twelve grains of pure carmin, and pour thereon three ounces of solution of ammonia; heat over a spirit-lamp for a space of from five to eight minutes, carefully regulating the temperature so that ebullition shall not occur, and to the solution thus formed, add, continually stirring, eighteen grains of powdered gum-arabic. When this is liquefied, the ink is ready for use. Drop lake may be substituted for the carmin, as being more economical.

According to OHME, a good red ink may be made by macerating, for two days, six drachms of powdered cochineal, and one ounce and a half of pure carbonate of potassa, with sixteen ounces of water. Four and a half ounces of bitartrate of potassa and three drachms of alum are then to be added, and the fluid heated as long as carbonic acid is evolved. After the liquid has been filtered, the contents of the filter are to be washed in one ounce and a half of water, and one ounce of alcohol is then added to the resulting fluid, as an antiseptic. For most purposes, six drachms of gum-arabic should be dissolved in each sixteen ounces of this ink; but when used as a tinctorial agent in confectionery, for which it is well fitted, the addition of gum is unnecessary.

Mr. STEPHENS obtains an excellent red ink from cochineal by the following method:—Add to a quantity of common carbonate of potassa, soda, or ammonia, twice its weight of crude argol in powder. When the effervescence caused by the combination of the tartaric acid of the argol with the alkaline base, thereby expelling the carbonic acid, has ceased, decant or filter the solution from the insoluble matter; to this is added, by measure, half its quantity of oxalate of alumina, prepared by dissolving damp, newly-precipitated alumina in as small a quantity as possible of a concentrated solution of oxalic acid. The mixture thus prepared is next colored, when cold, with bruised or powdered cochineal, and after standing for forty-eight hours is strained, when it is fit for use.

The Rev. J. B. READE took out a patent for a red ink in the year 1847. Subjoined is his mode of preparing it:—Cochineal is first boiled in successive quantities of pure water, till it ceases, or nearly so, to afford tinctorial matter. It is then subjected to ebullition with dilute ammonia, which dissolves the remainder of the tint-giving principle, leaving the animal matter nearly white. These aqueous and ammoniacal decoctions are then mixed in an earthenware vessel, and the coloring matter is then thrown down by means of the double chloride of ammonium and tin. The compound thus formed is subsequently boiled in ammonia, and iodide of tin is then added, till the required degree of brilliancy of hue is obtained; this completes the process, the degree of body required in the ink being given by an *ad libitum* addition of water. This ink, says the patentee, is greatly superior to the com-

mon solutions from peach and Brazil-wood, not only in permanent richness of color, but also in its freedom from acid, and consequent fitness for use with steel pens.

BLUE INK.—There appears to have been no true ink of a persistent blue color, until Mr. STEPHENS introduced his *unchangeable blue writing fluid*.

Reflecting upon the durable nature of Prussian blue, as well as upon its beautiful and strong contrast to white paper, Mr. STEPHENS was led into an investigation of the means of dissolving it, so as to adapt it to atramentation, while, at the same time, it might be made serviceable to the dyer; and oxalic acid was found to answer the purpose. The ink is prepared as follows:—Take Prussian blue—whether it is that of commerce, or purposely prepared by a combination of a sesquisalt of iron with ferrocyanide of potassium, is immaterial—put it into an earthen vessel, and pour upon it as much strong acid as will cover it. Hydrochloric, nitric, and sulphuric acids are equally of service; but if the latter be used, it should be diluted with a quantity of water equal to its own bulk. The Prussian blue is allowed to remain in the acid from twenty-four to forty-eight hours, or even for a more extended period; the mixture is then diluted with much water, at the same time agitating it, for the purpose of washing from it the salts of iron. When in this state of dilution, it is permitted to rest until all the color has subsided, at which time the supernatant liquid is siphoned off, and a further quantity of water added. This process is repeated until ferrocyanide of potassium no longer evinces the presence of iron by giving a blue precipitate; and also until the menstruum ceases to redden blue litmus paper, thus proving that the acid has been entirely removed. The product is then placed upon a filter, and suffered to remain until all the liquid has drained away. The Prussian blue, by this treatment, has lost a considerable proportion of its iron, and is now more readily acted upon and dissolved than in any other condition. After being gently dried, oxalic acid is added to, and carefully mixed with, the Prussian blue; cold distilled water is then poured, in small portions at a time, over the whole, making it into a dense or dilute solution, according to the depth of color required. The amount of oxalic acid may be varied according to the quantity of water used. It will be found that Prussian blue which has undergone the process of digestion just described, requires but a small modicum of acid to dissolve it. For a concentrated solution, six parts of Prussian blue—weighed before the treatment with acid—will, after the operation, be taken up by one part of oxalic acid, and a proportional amount of water. Prussian blue, in its ordinary state, will require two or three times its weight of oxalic acid; and even then, it will be liable to precipitation after standing; when deprived of a portion of its iron in the first place, by means of acid, it remains a permanent solution.

The comparative durability of the ordinary black ferrogallie ink and that made from the sesquiferrocyanide of iron—Prussian blue—may be judged of by the following:—

Black ink is a combination of a protosalt of iron

with the active principles of galls; the tannogallate of iron thus produced is good whilst the metal remains as protoxide; but, as soon as the salt has passed into a higher state of oxidation, the ink has a tendency to decay; and as still more oxygen is attracted and combined, the vegetal matter is decomposed, until eventually there remains on the paper only oxide of iron of a reddish-brown hue, similar to that produced when the ink is acted upon by chlorine. If the writing is kept from the air, and all damp is excluded, the color of the ink will be unaffected for many years; but should the manuscript be placed in a damp position, the iron soon passes into the state of sesquioxide, and the vegetal portion of the ink becomes extinct.

The ink from Prussian blue has a reversed principle as regards its permanence. While the iron is in its normal degree of oxidation, the color is only partially developed, and it is not until the iron is further oxidised by means of an acid, or by exposure to the atmosphere, that the fine deep hue is fully developed. It is here that the uniform well-known tendency of the lower oxides of iron to absorb oxygen, instead of being an evil, is of positive service. As the state of sesquioxide is the true condition in which iron combines with ferrocyanogen to give Prussian blue, and as the inherent disposition of the iron is to assume this form, it is clear that the tendency of the elements is to be permanent. As a further proof of this, if writing executed with Prussian blue ink be exposed for a longer or shorter period to the action of strong light, a deoxidation of the iron occurs, and the color is to all appearance faded; but, on removing it from the influence of light, the iron reassumes the state of sesquioxide, and the color again becomes dark: this change may be repeatedly effected in the same manuscript, with an unvarying result. This repeated deoxidation by light, and the reverse action from want of solar or other rays, is generally known and well exemplified in the case of articles of external dress dyed with Prussian blue, which, being worn—and consequently exposed to the influence of strong light, not the less powerful because coming from its primary source, the sun—become pale, and lose that brilliancy for which Prussian blue, as a tinctorial substance, is so celebrated; but when these habiliments are again brought out, after being exposed for some time to darkness, the color is revived as by magic, and is again equal to new.

On adding a solution of ferrocyanide of potassium to ordinary black ink, a blue hue results; the affinity of the iron for the ferrocyanogen being so much stronger than that which it has for the tannic and gallic acids, the latter are displaced, thereby showing the greater force of combination in the blue, over that in the black ink. Many acids are destructive of the color of the latter, but the sesquiferrocyanide of iron is unaffected by any. Even chlorine has no action upon it, except that it perhaps deepens the shade a little. Of excess of moisture and light, and of the thousand and one physical causes which operate destructively upon black ink, only one affects the preparation of Prussian blue—light, and the action of this, as has been seen, is far from being permanent.

The Rev. J. B. READE has also patented a blue ink, which is manufactured as under :—

A solution of iodide of iron having been carefully prepared according to the usual method, a proportion of iodine amounting to half the weight already employed, is dissolved therein, and the mixture is then poured into a semi-saturated solution of ferrocyanide of potassium, employing of this salt a quantity about equal to that of the whole of the iodine used in the first-mentioned menstruum. A decomposition of the materials thus brought together immediately takes place, the ferrocyanogen of the potassium salt combining with the iron, and falling down in a solid form ; while the potassium and iodine unite to form an iodide of the alkali-metal, which remains in solution, together with a slight excess of iodide of iron. The whole is placed on a filter ; the retained deposit, caused by the union of the iron with the ferrocyanogen, and which is nothing more or less than Prussian blue in a soluble state, is well washed with, and is finally dissolved in water, which forms the blue ink desired.

Dr. NORMANDY has proposed a blue ink, which is made by operating upon Chinese blue, or ferrocyanide of iron. Three drachms of the ferrocyanide are macerated in seven ounces of water, with one drachm of binoxalate of potassa, adding one drachm of gum-arabic. A solution of tin may be added to these ingredients ; the binoxalate of potassa may also be substituted by an equivalent proportion of oxalic acid.

OHME recommends the following formula for blue ink :—Dissolve one scruple of iron in nitrohydrochloric acid—aqua regia—filter the solution, and dilute it with sufficient water to make eight ounces, which is mixed with four drachms of ferrocyanide of potassium, previously dissolved in eight ounces of water. The resulting subsidence is collected on a filter, and after the fluid has, as far as possible, been removed, the precipitate isedulcorated with pure water, until the latter passes through, having an azure tint. As soon as this occurs, the funnel and its contents are placed over a clean vessel, the filter pierced, and the blue compound washed with twenty-four ounces, by weight, of water. This latter menstruum constitutes the blue ink, the formation of which depends on the property of the precipitate to dissolve in pure water, and not in solutions of other salts.

PURPLE INK.—To produce a purple-colored ink, called the *King of Purples*, Dr. NORMANDY recommends the following method :—To twelve pounds of Campeachy logwood, add as many gallons of boiling water ; pour the infusion through a funnel with a strainer made of coarse flannel, on one pound of hydrate or acetate of copper—verdigris—finely powdered ; at the bottom of the funnel a sponge is placed ; then add immediately fourteen pounds of alum, and for each seventeen gallons of liquid, add four pounds of gum-arabic or senegal ; let these remain for three or four days, and a beautiful purple will be produced.

GREEN INK.—KLAPROTH directs for the preparation of green ink, that two parts of acetate of copper and one of bitartrate of potassa be boiled in eight parts of water, till the solution be reduced to half the bulk. It is then filtered through cloth, and after cooling, bottled.

WINCKLER has given the following recipe for a green ink :—Dissolve one hundred and eighty grains of bichromate of potassa in one fluid ounce of water ; add to the menstruum, while warm, half an ounce of spirit of wine ; then decompose the mixture with concentrated sulphuric acid until it assumes a brown color. The liquor is now evaporated till it is reduced in quantity to one-half, when it is diluted with two ounces of distilled water, filtered, mixed with half an ounce of alcohol, subsequently with a few drops of strong sulphuric acid, and then allowed to rest till, after some time, it assumes a beautiful green color. It is finally adapted for use by the addition of a small quantity of gum-arabic.

OHME has devised a green ink, made by triturating one drachm of gamboge with one ounce of the blue ink invented by him, and previously noticed ; but it is of little value.

YELLOW INK.—Yellow ink, according to Dr. URE, is prepared by dissolving three parts of alum in one hundred parts of water, adding twenty-five parts of bruised Persian or Avignon berries, boiling the mixture for an hour, filtering the liquor, and dissolving in it four parts of gum-arabic.

An extemporaneous yellow ink may be made by dissolving gamboge in water, but it is by no means permanent.

GOLD AND SILVER INKS.—Gold ink is prepared as follows :—Grind upon a porphyry slab with a muller, gold leaf and fine white honey, till the former is reduced to an impalpable powder. The paste is then carefully collected and diffused through water, which dissolves the honey, causing the deposition of the precious metal ; the water must now be decanted, and the sedimentedulcorated to free it from the saccharine matter. The powder exsiccated is very brilliant, and when required for use is suspended in mucilage of gum-arabic. After the writing executed with this ink is dry, it should be burnished with ivory.

Silver ink is prepared in the same manner, by substituting this metal, in leaf, for the gold.—*Ure*.

INDIAN OR CHINESE INK consists essentially of lamp-black formed into cakes by means of some glutinous or adhesive substance, such as gum-water. The lamp-black is said to be made in China by collecting the smoke of the oil of sesamé ; and M. MERIMÉE states that the Chinese do not use glue in the fabrication of their ink, but certain vegetable juices, which render it more brilliant and more indelible upon paper. Dr. URE remarks, that when the best lamp-black is levigated with the purest gelatin or solution of glue, it forms, no doubt, an ink of a good color, but wants the shining fracture, and is not so permanent on paper as good China ink. In the latter has been detected about two per cent. of camphor, which is supposed to improve it. On the other hand, PROUST says that lamp-black, purified by potash lie, when mixed with a solution of refined glue, and dried, formed an ink which was preferred by artists to that of China. A good Indian ink may be made with ivory black, ground to a fine powder, made into a paste with weak gum-arabic water, and then formed into cakes.

MARKING INK.—The fluids for writing on linen now known are widely different from those in vogue even

a few years ago. The latter always required a preparation of the tissue, previous to their application. The formulæ for a few of these are given, not so much on account of the likelihood of their being again useful, as to give an insight into their composition, thereby showing what science has accomplished even in such a limited sphere.

Marking inks are of two kinds: the first of these is applied with the pen, the second with types.

One of the older marking inks, in using which the linen required to be *pounded* or prepared, is as under:—Dissolve one hundred grains of nitrate of silver, two drachms of gum-arabic, and one scruple of sap green in one ounce of distilled water. The linen is to be wetted before applying this, with a pounce, consisting of a solution of one ounce of carbonate of soda in eight of distilled water.

GRAY directs that the ink be composed of two drachms of nitrate of silver, six drachms of water, and two of mucilage, while one ounce of carbonate of soda in sixteen of water, together with a little sap green, form the pounce. Another ink is a solution of one drachm of nitrate of silver, one of mucilage, in five drachms of distilled water, tinged slightly by means of sap green. The pounce consists of, carbonate of soda, one ounce; gum-arabic, one ounce; water, six ounces.

A form of ink known as Italian is merely terchloride of gold, the cloth being moistened before its application with a solution of chloride of tin.

The modern marking inks do not require the pounding of the linen previous to its being written upon; but instead, a hot iron is passed over the marks, or the cloth is held near the fire, till the color has been properly developed.

REDWOOD gives the following as the requisite properties of marking ink:—

1. That it shall flow freely from the pen, and form a well-defined mark, without running or blotting.
2. That it shall not require the application of a very strong or long-continued heat, by holding the article that has been written on to the fire, or by passing a hot iron over it, to develop the required hue.
3. That the marks produced by it, when brought out by heat or by exposure to light, shall be perfectly black.
4. That it shall not injure the texture of the finest cambric.

Subjoined is a very common formula for this kind of ink:—

Six drachms of nitrate of silver are dissolved in three ounces of distilled water, and as much ammonia is added as will liquefy the precipitate which it at first occasions. A little sap-green, ivory-black, Indian ink or indigo, diffused through four drachms of mucilage of gum-arabic, form the temporary tinctorial matter, and water is added to make up the quantity to four ounces.

Many marking inks, although black when first applied to the linen, become gradually washed out, and a yellowish stain only remains. JULES GUILLER has given three recipes for marking ink, which he believes to be free from these and some other prevalent evils. They are as under:—

For the first ink, twenty-two parts of carbonate of

soda are dissolved in eighty-five of distilled water, and twenty parts of pulverized gum-arabic are diffused through the menstruum. Eleven parts of nitrate of silver are then liquefied in twenty parts of ammonia, and this is commingled with the alkaline solution. The mixed fluids are next warmed in a flask, by which they become greyish-black, and partly coagulated; subsequently, brown and clear; then, when ebullition commences, very dark, and of such a consistence that it will flow readily from the pen. This ink, and that prepared from the next formula, have the advantages that no precipitates are formed in them, and that they insipitate by boiling, whereby their color becomes darker. For the second ink take,—

	Parts.
Nitrate of silver,.....	5
Distilled water,.....	12
Powdered gum-arabic,	5
Carbonate of soda,.....	7
Ammonia,.....	10

Treat these ingredients in the manner last described, and heat the resulting mixture in a flask until it has acquired a very dark tint, which is generally the case when its volume has diminished, by evaporation, about five per cent. By continuing the evaporation too long, a precipitate is occasioned in consequence of the loss of volatile alkali. The ink prepared in this manner is distinguished by producing very black characters upon linen, and is very suitable for marking with stamps or stencil-plates.

According to the third prescription, twenty-two parts of carbonate of soda are dissolved in twenty-five of distilled water; as also seventeen parts of nitrate of silver in forty-two parts of ammonia. Twenty parts of gum are then liquefied in sixty parts of water, and mixed with the soda solution, and afterwards with that of nitrate of silver, and lastly, thirty-three parts of sulphate of copper are added.

The large quantity of ammonia in this ink, says GUILLER, is accounted for by the presence of the cupreous salt. The latter might be replaced by nitrate of silver, but a much larger amount of this would be required to render the ink as dark as it is with the sulphate of copper. Whilst other marking inks have a dark-brown color, this ink possesses a rich blue. The proportions of the ingredients in these inks can be altered according to the consistency required, the uses to which they are to be applied, or the description and quality of the textile fabric on which they will be deposited.

REDWOOD's ink, which answers all the conditions—given above—that a marking ink ought to possess, is prepared in the following manner:—

Dissolve one ounce of nitrate of silver, and one and a half of crystallized carbonate of soda in separate portions of distilled water, and mix the solutions; collect the resulting precipitate on a filter, edulcorate it well with distilled water, and introduce it, while still moist, into a Wedgwood-ware mortar; add eight scruples of tartaric acid, and triturate the whole until effervescence has ceased: next add a sufficient quantity of ammonia to dissolve the tartrate of silver; mix in four fluid drachms of archil, four drachms of white sugar, and twelve of finely-powdered gum-arabic; and pour

in as much distilled water as will make six ounces of mixture.

The essential distinction between this and ordinary inks is the use of tartrate instead of nitrate of silver.

Long after REDWOOD had published his formula, generously laying his invention open for public use, the Rev. J. B. READE devised and patented two inks, the principle of which was identical with that of REDWOOD. Happening to meet with an ink made according to REDWOOD's recipe, he threatened the manufacturer with legal proceedings; but was prevented doing so by REDWOOD's showing with whom the invention originated. As other compounds are implied in Mr. READE's inks, the formula for each is appended:—

The first of these, which may be used with steel pens, and which is most readily developed on the application of heat, is prepared in the subjoined manner:—Nitrate of silver is triturated in a mortar with an equivalent of desiccated tartaric acid. Water is then added, which causes the separation of crystals of tartrate of silver, nitric acid being set free. The latter is neutralized carefully by adding ammonia, which also dissolves the metallic tartrate. Gum, tinctorial matter, and water are subsequently added in quantities which may be varied at pleasure.

By this process, remarks the patentee, the nitric acid, which is essential to a good marking ink, is retained, and the tartrate of silver formed is soluble in half the quantity of ammonia ordinarily required when nitrate of silver is the basis of the ink.

The second of the inks under this patent is made as follows:—

To a portion of ink formed by the process last described, is added an ammoniacal solution of an oxide, or salt of gold. The patentee has employed for this purpose the purple of Cassius—formed by precipitating a solution of the terchloride or other salt of gold by means of a tin salt—sulphide of gold, the iodide of gold and ammonia, and also the teriodide of gold and ammonia. The last two compounds, which Mr. READE considers to be *new*, he obtains by dissolving iodine in ammonia with application of heat; this operation must be conducted with great caution, in order to prevent the formation of that explosive compound, teriodide of nitrogen. The iodine solution thus obtained is a valuable solvent for gold. If this metal, in leaf, be placed upon it without the addition of water, a black deposition of gold is formed, which immediately dissolves; but, if the menstruum be diluted, the oxidation proceeds less rapidly, and the gold leaf assumes before solution, not a black, but a fine purple color. This salt of gold crystallizes in four-sided prisms, soluble in water. A few drops of this solution placed on a slip of glass, generally form arborescent, microscopic crystals, from which, by application of heat, the iodine and ammonia are volatilized, and arborescent metallic gold alone remains. If the heat be applied but moderately, only one equivalent of iodine is dispelled, and white crystals of iodide of ammonium and gold are left.

A *purple-red* marking ink consists of a solution of one drachm of bichloride of platinum in two ounces of distilled water. Before writing with it, prepare the

linen with a pounce made by liquefying three drachms of carbonate of soda and three drachms of gum-arabic in an ounce and a half of water.

SYMPATHETIC INK.—By sympathetic ink is meant a fluid which, being employed in writing, does not leave a trace of color upon the paper, but which, when exposed to moisture or heat, or when washed over with some vegetal or mineral solution, or subjected to some other agency according to its nature and chemical characteristics, becomes visible, the characters being then developed in a more or less apparent manner.

OVID mentions the method of writing with new milk, the characters being subsequently developed, even after the lapse of some time, by coal-dust or soot. The same means are proposed by AUSONIUS. It may be easily perceived that instead of milk, any other colorless and glutinous juice might be employed, as it would equally retain the black powder sprinkled upon it. PLINY, perceiving this, recommends the milky sap of certain plants.

Of all sympathetic inks, none, perhaps, is more remarkable than a solution of acetate of lead. The delineations made by this menstruum are rendered intensely black by means of sulphide of hydrogen—known also as hydrosulphuric acid, and as sulphuretted hydrogen—whether it be in a gaseous or liquid state. This effect, remarks BERGMANN, presented itself, perhaps accidentally, to some chemist; but the discovery is not of great antiquity. The first person who gave a receipt for preparing this ink, as far as the historian just quoted could learn, was PETER BOREL. In a work by him, printed in 1653, and again in 1657 at Paris, of which there were several subsequent editions, it is called a magnetic water which acts at a distance. In these days, phenomena, the causes of which were unknown, and particularly those which seemed to occur without any visible agency, were ascribed to *magnetic effluvia*. Others concealed their ignorance under what they called *sympathy*. The recipe for making these liquids, under the name of sympathetic ink, is first given by LE MORT, and that cognomen has not only been retained with reference to a solution of acetate of lead, but has also been applied to other fluids when employed for the same purposes.

Another and more beautiful sympathetic ink is that prepared from cobalt, the writing of which disappears in the cold, but appears again of a rich green color, as often as one chooses, after being exposed to a moderate degree of heat. This invention is generally ascribed, writes BERGMANN, to the French chemist HELLOT. He was, indeed, the first person who, after experimenting with it, made it public, but he was not the discoverer; he acknowledges that a German artist of Stolberg first showed him a reddish salt, which, when exposed to heat, became blue, and which, he assured him, was made out of Schneeberg cobalt with aqua regia—nitro-hydrochloric acid; but, if it be true that THEOPHRASTUS PARACELSUS could represent a garden in winter by this invention, it must unquestionably be older.

The development of chemistry in modern times, and the consequent discovery of an immense number of chemical compounds, have given rise to an almost infinite

variety of sympathetic inks. Some of the principal ones will be described:—

Black,—write with a solution of acetate of lead, or ternitrate of bismuth, and wash the writing over with an aqueous solution of sulphide of hydrogen, which causes the formation of sulphide of lead in the first instance, and of tersulphide of bismuth in the latter case. Or chloride of mercury may be used as the ink, to be developed by being placed in contact with chloride of tin; metallic mercury, in a minute state of division, being thus thrown down. A sympathetic ink, identical with common black writing fluid, consists of a solution of sulphate of iron; tincture or decoction of galls being employed as the mordant.

Blue,—employ nitrate of cobalt as the ink, with oxalic acid as a mordant—in this case oxalate of cobalt is formed; or sulphate of iron may be used for writing, which is to be washed over with ferrocyanide of potassium.

Yellow,—use chloride of antimony as the ink, and moisten the writing with decoction of galls; or inscribe the characters with subacetate of lead, and develop them by means of hydriodic acid. A dilute solution of chloride of copper forms a beautiful sympathetic ink, which is invisible until gently heated, when the letters assume a fine yellow color, which disappears as the paper cools.

Green sympathetic ink consists simply of a solution of chloride of cobalt, with a small quantity of a salt of nickel. Writing done with the colorless arseniate of potassa, and washed over with nitrate of copper, becomes beautifully green.

Purple is produced by edulcorating, with chloride of tin, writing executed with chloride of gold, the *purple of Cassius* being in this case formed.

The substances which may be employed as sympathetic inks, either *per se* or in conjunction with others, are exceedingly numerous; but they are so generally known that it is needless to describe them.

LITHOGRAPHIC WRITING INK.—There are two kinds of ink used in lithography,—that which is employed by the lithographic writer in tracing an inscription or design on paper with a view to its subsequent transference to the stone; and that which is employed in taking impressions on paper from engraved plates with a view to the same object. The composition of the latter will be stated under Printing Inks. The writing ink is composed of ingredients mixed in the following proportions:—For one and a half ounce of shellac, take two ounces of soap, three ounces of white wax, and about one ounce of tallow; add about three tablespoonfuls of a strong solution of gum-sandarach, and when ready color with lamp-black.

PRINTING INKS.—*Encre d'imprimerie*, French; *Buckdruckerfarbe*, German.—Printing ink, though of greater importance than that used for writing, has not engaged the attention of scientific men to any extent, and few works have been published respecting it. No printers of the present day make their own ink, although many add ingredients which they believe to improve the color or quality. It is an especial business, and demands considerable capital. Every manufacturer has his own secrets, both as to material and process; and

by long experience alone can printing-ink makers so select and apportion the various ingredients as to adapt it to its numerous requirements.

The commonest book-ink costs eighteenpence per pound, while the usual qualities are from two shillings and sixpence to four shillings; black ink for superior work is worth five to six shillings, while for the finest carmine ink as much as thirty shillings per pound is paid. In the latter case, the value of the tinctorial matter enhances the cost; but, when the care and labor required in the preparation are taken into consideration, it is evident that it is not the mere value of the ingredients which fixes its price.

PROPERTIES.—Printing ink, as every one must be aware, is a very different composition from that used for writing. It is a soft, glossy compound, having a certain amount of adhesiveness, and becoming, by exposure in thin layers, perfectly hard and firm. Besides these properties, which always belong to it, it possesses other and varying attributes according to the numerous purposes to which it is applied. Its preparation demands not only a tolerable proportion of scientific knowledge, but also very careful manipulation; and manufacturers have found that, to produce it of good quality, both experience and deep study are requisite. The very important use for which it is designed—the registering in a permanent manner the productions of the mind—indicates some of the properties it ought to possess. The most valuable of these is durability, or the capacity to resist successfully the obliterating influence of time; and it ought, at the same time, to have brightness and depth of tint. It must be a mutable preparation, passing from the soft adhesive state to that of a perfectly hard and dry substance, and this change of condition must have a certain rate of progress, and be to some extent under control. When prepared, some time generally elapses before it is used, and during this period it ought not to alter in the slightest degree; in fact, when the air is excluded from it, it should keep for almost any length of time. During its application to the types, its solidification ought to be as slow as possible, and unaccompanied by the emission of any unpleasant or deleterious odor. It ought not to affect the soft, elastic rollers which are employed to convey it to the type or woodcut *form*, and which, unless the ink be a perfectly innocuous preparation, are liable to considerable injury. The change of state should not be accompanied by the deposition of consolidated matter in the ink, as this impedes the workman, and proves a loss to the printer.

The trying circumstances, as regards the quality of printing ink, do not end here. Having been applied, its action must be confined to a very slight penetration into the paper,—just sufficient to prevent its detachment without materially injuring the surface of the latter. It ought to dry up, in a very short space of time, to a hard, inodorous, unalterable solid.

Printing ink should, moreover, have an oleaginous character; it ought to be very glossy, and perfectly free from any granular appearance. If, on the extraction of a small portion from a mass, it leaves but a short thread suspended, it is considered good; but the best

test of its consistency is the adhesion it shows upon pressing the finger against a quantity of it.

MATERIALS.—The ingredients of ordinary printing ink are *burnt* linseed oil, resin, and occasionally soap, with various coloring matters. A slight notice of these is required.

Linseed Oil.—The best quality of oil is used, and this is purified by digesting it in partially-diluted sulphuric acid for some hours, at a temperature of about 212°, allowing the impurities to subside, and then washing away the acid with repeated additions of hot water. The oil after this treatment is pale and turbid, and, if the edulcoration is complete, there is scarcely any odor. By rest the oil clarifies, and has then a pale lemon color. It now dries much more rapidly than before. For an experiment, four drops of oil were exposed on a slip of glass: the first was ordinary Baltic linseed oil; the second was East India oil; the third and fourth were two distinct oils which had been purified by means of sulphuric acid. In the course of a fortnight, the first was colorless and rather viscid, but no skin or pellicle had formed on its surface; the second was colorless, but had no apparent viscosity; the third and fourth were not only colorless, but a tenacious film covered the surface of each.

The purified oil is now partially resinated by heat. For this purpose it is introduced into large cast-iron pots, and boiled until inflammable vapors are freely evolved. These are ignited, and allowed to burn for a few minutes, after which they are extinguished by placing a tight cover over the boiler. Ebullition of the oil is continued until, on cooling, a firm skin forms on its surface, known by placing a drop on a slate or other smooth cold material.

According to SAVAGE,—who has written at considerable length on this subject, and whose inks gained the large medal of the Society for the Encouragement of Arts,—the linseed oil cannot be brought, however long boiled, unless inflamed, into a proper state for making printing ink. Certain it is, that by the ebullition and ignition just noticed, the original character of the oil is totally altered; it is at first turbid, but clarifies when allowed to repose; it is now viscid and more or less adhesive; it penetrates paper with difficulty; it dries much faster than when unburnt; and it has now a pyrogenous and not unpleasant odor, which soon passes off from a thin layer exposed to the air. Fragments of slightly charred bread are by some added to the boiling oil, but no marked benefit arises from such a procedure.

Other drying oils besides linseed are occasionally used, but their cost or other considerations prevent their general adoption. Resin oil is indeed pretty largely employed by some makers; but, apart from other disadvantages, its disagreeable and permanent smell prevents its entering into other ink than that intended for temporary or common printing, as newspapers, placards, *et cetera*.

Resin is an article of considerable importance in the manufacture of printing ink, since, when dissolved in the oil—after the latter has undergone ebullition and inflammation—it communicates *body* to the fluid, and the compound bears a great resemblance to Canadian balsam. For many inks, the quality of the common

black resin is sufficiently good; but some require the pale, clear, transparent resin, obtained by remelting and clarifying the residue of the distillation of turpentine with water.

THE COLORING MATTERS of printing ink demand great attention, as much of the beauty of the typography depends upon them.

Black.—The universal ingredient for this color is lamp-black. There are vast buildings, as a writer in the *Encyclopedia Britannica* remarks, appropriated to the sole purpose of burning oil, naphtha, spirit, coal-gas, *et cetera*, to produce this black, which is collected from the sides and ceilings of the chambers. It is imported from Germany and many other countries, and no expense is spared to get the most superior quality.

Other black substances are occasionally employed. Charcoal from various sources, when reduced to an impalpable powder, and mixed with the other ingredients, furnishes a deep blue-black ink that dries rapidly. Carbonized vine-stalks, wine-lies, woods of various kinds—in fact, carbonized lignin from any source, when ground sufficiently fine—sometimes a tedious and costly operation—answer well; as also does bone-black. The brown tint possessed by lamp-black is not unfrequently neutralized by the addition of blue compounds, as indigo, Prussian blue, *et cetera*.

For *red* ink, carmin, lake, vermilion, red lead— Pb_3O_4 —Indian and Venetian red, are employed.

A *blue* color is supplied by Prussian blue, indigo, Antwerp blue, *et cetera*.

Chromate and bichromate of lead—known respectively as lemon and orange chrome, or as chrome yellow and chrome red—yellow ochre, gamboge, and other pigments, furnish a *yellow* hue.

Green is obtained by means of arseniate of copper, or by a union of blue and yellow colors.

For *brown*, burnt sienna, umber, sepia, and mixtures of red with black, are employed.

PREPARATION.—In the manufacture of printing ink, the resin is dissolved in the burnt oil, in cast-iron pots or boilers, and the varnish, thus prepared, is introduced into what is termed *the mixing vessel*, which is cylindrical, and in the centre of which, bars or rods of iron, attached to a perpendicular shaft, revolve in a horizontal position. The black or other coloring matter is then added to the hot varnish, and the whole, when thoroughly mixed, is drawn off through an opening in the base of the vessel. The *pulp* is next very carefully ground, by being passed between hard stones of a very fine texture, driven by heavy machinery, the motive power being steam. Sometimes a second grinding is requisite, but this may generally be avoided by taking care that the varnish of resin and oil is clear and free from gritty particles, and that the black is in an impalpable state.

The proportions and conditions of the various ingredients vary considerably, and great experience is required before an ink can be prepared to suit any one purpose. The oil has to be rendered more viscid, by burning, in some cases than in others; sometimes the quantity or kind of resin requires to be varied; or, perhaps, different proportions of color are requisite. Newspapers printed by steam-power require an ink of

less substance than that employed for book-work, which must be tolerably *stiff*. For woodcuts, the ink must not only be stiff, but very fine. The qualities of the material to which the ink is applied, furnish an additional guide in this matter: thin paper must have a soft ink, which *works clearly*, and is not too adhesive. A fine stout paper, on the other hand, will bear a stiffer and more glutinous ink; and as resin supplies these properties, so does it in a great measure communicate brilliancy, and the most perfect and splendid effects are by these means produced.

URE gives the following directions for making printing ink:—

To one and a half gallon of linseed oil, burnt and boiled, as above described, till a portion, extracted from the pot by means of a pallet-knife and cooled, draws out between the fingers into strings of about half an inch in length—add gradually six pounds of resin. When this has dissolved, twenty-eight ounces of dry brown soap of the best quality, cut into slices, are introduced cautiously, for the combined water causes a violent intumescence. Both the resin and soap are well stirred in, and the whole is then ignited for a few moments, in order to complete the admixture of the constituents. Two and a half ounces each of ground indigo and Prussian blue, together with four pounds of the best *mineral* lamp-black, and three and a half pounds of good *vegetal* lamp-black, are placed in an earthenware pan, sufficiently large to contain the whole of the ink, and the warm varnish is then added by degrees, carefully stirring, to produce complete incorporation of all the ingredients; and the mixture is, finally, ground into a smooth uniform paste.

The two succeeding recipes are from the *Encyclopædia Britannica*, the first being that used by BASKERVILLE and BULMER, and giving excellent results:—

1. Dissolve a small quantity of black or amber resin in three gallons of fine old linseed oil, which has been boiled to a thick varnish, and cooled in small quantities; allow the mixture to stand for some months, so that all impurities may subside, then mix with the best lamp-black, and grind carefully.

2. One hundred pounds of nut or linseed oil are reduced by boiling and burning to one-eighth its bulk, and to the consistence of a sirup; two pounds of coarse bread and several onions (!) being thrown in to purify it from grease. Thirty or thirty-five pounds of turpentine are boiled apart, until, when the residue is cooled on paper, it breaks clean, without pulverizing. The former is poured nearly cold into the latter, and well mixed. The compound is then boiled again, a sufficient quantity of lamp-black is incorporated, and when the ink is well ground, it is ready for use.

One pound of printing ink may be made by the subjoined recipe of SAVAGE:—

Balsam of copaiba, nine ounces; lamp-black, three ounces; indigo and Prussian blue, ground together in equal proportions, one and a quarter ounce; Indian red, three-fourths of an ounce; dry, yellow turpentine soap, three ounces: this mixture is to be ground, by means of a slab and muller, to an impalpable smoothness. It is stated that this ink possesses a beautiful color, but appears to work foul.

VOL. II.

JOHN BIRD took out a patent for substituting a mineral found in Merionethshire and other localities, instead of lamp-black. The mineral is freed from *debris* by washing, when it becomes a very black paste; and subsequently, on drying, a fine, black, impalpable powder, composed of—

	Centesimally.
Silicic acid,	46·00
Alumina,	42·00
Carbonaceous matter,	12·00
	100·00

The preparation of printing ink with this pigment is, in other respects, according to ordinary methods.

A patent was granted in 1854 to THOMAS DE LA RUE, by which glycerin is employed as a vehicle for making a fugitive ink, peculiarly applicable for the printing of bankers' cheques and other similar documents. For this purpose he precipitates logwood and vegetal substances, suitable for producing coloring matters, and grinds them up with glycerin to the consistency of ordinary printing ink.

The Rev. J. B. READE'S patents for printing ink are as under:—

He describes two blue printing inks: the one is made by taking the soluble Prussian blue obtained in the manufacture of his blue writing ink, and rubbing it up with oil; or, by triturating with oil the residue obtained by evaporating his blue ink.

For the second blue ink, he prepares the soluble Prussian blue with bromine instead of iodine, and diffuses it in oil.

His first *black* printing ink is made in like manner from his black writing fluid.

A second black printing ink is made by boiling chips of logwood—for which an extract of logwood may be substituted—or other dyewoods containing coloring matter and tannin, with as much proto- or persalt of iron or of copper, as will be equal to about twice the weight of the tannin contained in the wood or extract employed; a black or bluish-black precipitate is thus obtained, the blueness of which is diminished, as required by the addition of a greater or less quantity of bichromate of potassa. The whole is finally triturated with oil; a little lamp-black, or other black coloring matter usually employed in the manufacture of printing inks, being added.

LITHOGRAPHIC PRINTING INK.—The composition of lithographic writing ink has been already given. That which is employed to take impressions on paper from engraved plates, with a view to their transference to the stone, may be composed as follows:—Tallow, wax, and soap, of each four ounces; shellac, three ounces; gum-mastic, two and a half ounces; black pitch, one ounce and a half; to which add lamp-black to color.

The Editor cannot conclude the present article without expressing his thanks to Mr. HENRY STEPHENS, for his kindness in supplying him with information respecting writing inks; and also to Messrs. BENJAMIN SMITH and Son—who make the ink with which this work is printed, and who have a world-wide fame for the excellence of their productions—for similar favors with regard to printing ink.

3 C

IODINE.—*Iode*, French; *Iod*, German; *Iodium*, Latin.—This body is one of those which chemists designate elements, from the circumstance, that by no means or agency at their disposal are they enabled to extract any other form of matter from it. It may be regarded as a new substance, being discovered by M. COURTOIS, manufacturer of saltpetre—nitrate of potassa—in Paris, in the year 1812-13; and of all the simple bodies which have attracted the attention of chemists, iodine seems to be the most interesting, as, since its isolation, it has never ceased to present wide fields of investigation to the chemist and physician; many of these have been diligently explored and cultivated, but still sufficient remain untrodden to keep alive that scientific interest with which iodine has been invested from the date of its discovery. It is well known that chemistry has extended her domain of research principally during the last forty years; but even anterior to that period, chemical knowledge was so far advanced that the discovery of iodine might have been expected to take place long before its announcement by COURTOIS. That this should not have been the case is the more surprising, when the wide range of its distribution is considered, and its presence, particularly in reagents which the chemists of 1800, and their predecessors, were in the habit of using and preparing in a state of comparative purity; moreover, its characteristic appearance in the form of vapor, its odor, and the remarkable reactions which it produces, render the circumstance of its having escaped observation the more striking. The discovery of iodine is interesting, inasmuch as it was not a result arrived at by unguided experiment, as in the case of many bodies which might be cited, but of patient research. The multiplied unsuccessful attempts of COURTOIS to isolate it would be tedious to relate; but some idea may be formed of his numerous experiments and failures, from the first observation he made relative to the destruction of his copper pans employed in the decomposition of nitrate of lime with the alkaline lie of the varec or kelp, till he succeeded in tracing the effect to the cause, and in preparing iodine in a very pure state from the mother waters of his various processes. This discovery was made, as already stated, in 1812, and was announced by M. CLEMENT DESORMES at the meeting of the Institute on the 29th November, 1813. At this period iodine was anxiously sought after and studied by the celebrities of the day. By degrees it came to be known that other substances besides the ashes of sea-plants contained it, and since then numerous researches have shown that iodine is one of the most widely-disseminated elements, although, it may be remarked, that its aggregate amount is comparatively small. In the mineral kingdom it is met with, combined with silver and mercury, in ores from Mexico; in Silesian galmei it is found combined with zinc; and it has been detected in species of lead ore from South America; it is contained as iodide of potassium or sodium in the nitrate of soda from Chili, and has been detected similarly combined in the rock-salt of Hall in the Tyrol. Many springs have been found to yield quantities of iodine, united, doubtless, with the alkali metals, potassium and sodium, and with mag-

nesium; of this description are the waters of Bex, Sülze in Mecklenburg, Rolberg in Pomerania, Salzuffeln in Königsbrunn, near Unna, Rehme, near Minden Schönebeck, Halle in Saxony, Dürrenberg and Kösen, Artern and Salzingen, Schonalkalden, Salzhausen and Kreuznach, Bolechow and Drochobycz in Galicia, Kenahwa in North America, Guaca in the province of Antioquia in New Granada. Its presence has likewise been proved in the following mineral waters; namely, in the thermal spring of Albano, in one near Sales in Piedmont, in several salt springs near Ascoli, in the hepatic waters of Castel Nuovo d'Asti, in the hot spring of Aix in Savoy, in the Bonnington water near Leith, in Bath water, in the water from Marienbad in Bohemia, and also in the waters from Carlsbad, Heilbrunn, and Kunzig in Bavaria; in the medicinal waters of Hall in Austria, used for the cure of goitre; in the hepatic water of Trutkawiec, and in the alkaline waters of Iwonicz in Galicia. Besides these, later investigations have proved its presence in several other waters of every description. A vast amount of iodine exists in the ocean; but, from the minute centesimal proportion in which it is present, DAVY, GAULTIER, FYFE, and others, failed to detect it. In the plants which grow in the sea, as well as on its shores, the iodine is, so to speak, concentrated, and consequently, when the ashes of these are submitted to the usual tests for its detection, its presence is readily manifested. The following plants were found by SARPHATI to contain iodine in the quantities mentioned:—

	Per Cent.
<i>Fucus filum</i> ,.....	0.0894
“ <i>digitatus</i> ,.....	0.1350
“ <i>saccharinus</i> ,.....	0.2300
“ <i>nodosus</i> ,.....	—
“ <i>vesiculosus</i> ,.....	0.001
“ <i>saccatus</i> ,.....	0.124
<i>Loriscus siliculosus</i> ,.....	0.142

DAVY, GAULTIER, and FYFE found iodine in the following:—*Fucus cartilagineus*, *membranaceus*, *rubens*, and *palmatus*; according to SARPHATI, it is contained in *Sphærococcus crispus*; he found it also in *Ulva Linza*, *pavonia*, *umbelicalis*; likewise in *Lactuca* and *Zostera marina*. *Lichen confinis*, *Statice armeria*, and *Grimmia maritima*, growing upon rocks on which sea-water has been blown by the wind, have yielded this element; but *Ramelina scopulorum*, growing in the same situation, gave no indication to DICKIE of the presence of iodine. *Pile marina* contains it; and it is obtained in large quantities from the ashes of various species of *Fucus*, *Ulva*, and other sea-plants, which constitute the varec of Bretagne, and the kelp of the Scotch and Irish. The ashes of several shore-plants, such as the different kinds of *salsola*, and such as are used for producing the barilla of Spain and the Sicilian soda, contain very little or no iodine.

The marine animals which yield iodine are:—The Common sponge, the Horse sponge, *Lapis spongiarum*, *Spongia oculata*, *Flustra foliacea*, various species of *Sertularia* and *Tubularia*, various kinds of *Rhizostoma* and *Cyana*, *Asterias rubens*, *Crogon vulgaris*, *Mytilus edulis*; oysters contain it, and likewise various species of *Dorus* and *Venus*. It is found in cod-liver oil; and the oil from the liver of the *Raja clavata* and *Raja*

balis give indications of its presence; and from the statements of JONAS, it appears that traces of it are afforded by Scotch salt herrings. Besides these, many other substances of the animal and vegetable kingdom contain small traces of this element. Lately it has been detected in the ashes of various coals and shaly matters; and from the researches of M. CHATIN and others, it has transpired that rain water, dew, air, rose leaves, *et cetera*, give to properly-regulated experiments appreciable traces of iodine.

PROPERTIES.—M. GAY-LUSSAC was the first who investigated and discovered the general properties of this element, being succeeded by Sir HUMPHREY DAVY, VAUQUELIN, and several others. To prepare iodine, varec or kelp is exhausted with hot water, which dissolves about one half of this substance; the liquid is filtered and concentrated, and the chief part of the chloride of sodium, sulphate of soda, chloride of potassium, and other salts, is crystallized out, leaving a mother-liquor which, besides the iodide of sodium, retains other bodies in solution, such as sulphide of sodium, hyposulphate of soda, and traces of those already mentioned. This liquid is treated with sulphuric acid in a retort, when the more unstable compounds are decomposed, and sulphates of the bases produced; and on the application of a gentle heat, the iodine passes over into the condenser. In this state it is rarely pure, but is contaminated with chlorine, sulphur, and saline matters; it may be purified from these, however, by washing with water, filtering, and pressing between folds of bibulous paper, then subliming it a second time. A better method is to dissolve the iodine in alcohol, filter from any residue, and precipitate with water. The deposit collected and dried in the usual way, is pure iodine.

So prepared, it presents a bluish-black appearance, and a metallic lustre very similar to that of black-lead or specular iron ore. It is generally obtained in crystals, which are modifications of an elongated octahedron with a rhomboidal base, the primary form be-

evaporation in very small quantity, but which is increased when the air is loaded with moisture. When in a thin stratum, the vapor of iodine presents a beautiful rich violet shade from which its name is derived; but if examined in layers a few inches thick, it no longer presents this appearance, but rather a black mass, impervious to diffused day or candle light. Vapor of iodine is the heaviest of all known gases, being, according to the investigations of DUMAS, of specific gravity 8.717, and by calculation from its atomic weight, 8.7077. Alcohol and ether dissolve it in all proportions, producing dark reddish-brown liquids; water takes up only one seven-thousandth of its weight of this element. The solvent action is increased, however, when there are other salts dissolved in the liquid, such as nitrates or chlorides. In either case a brownish liquid is formed, which, by long exposure, disappears, the iodine being transformed into iodic and hydriodic acids. It is capable of uniting with most of the non-metallic elements, producing with some—such as nitrogen—highly explosive compounds; and with others—oxygen and hydrogen—acids which are capable of neutralizing bases, and thus forming salts, many of which are very important. The mineral acids, chlorine and several other bodies, are capable of displacing and reducing these compounds of iodine, and of setting the latter free when it colors the liquid brownish-red. A characteristic and remarkable property of iodine discovered by MM. COLIN and GAULTIER DE CLAUVERY, is the blue coloration it affords when brought in contact with starch-paste disseminated in water. This is so delicate and characteristic, that it still remains the test for iodine in all investigations, affording, according to STROMAYER, a perceptibly blue tinge when not more than one four hundred and fifty-thousandth part of iodine is contained in the liquid. KERSTING has latterly discovered that, by the use of a palladium salt, so small a quantity as the millionth part of iodine may be detected in a liquid. This subject will

be referred to further on. The starch test should be applied with some caution, however, as a large excess of the amylaceous substance causes the blue coloration to vanish. Heat also destroys it; and hence, in testing for iodine, the liquids must be cold. This reaction is not produced by iodine when combined with other bodies; and, consequently, when such combinations of iodine are to be examined, they should be decomposed

by some strong mineral acid—sulphuric or nitric, which contains a little nitrous acid.

Iodine is a most valuable therapeutic agent, and, as such, was first brought into notice by COINDET, a distinguished physician of Geneva, who found it a most effectual remedy for goitre. Its application is very frequent, more especially in diseases of the skin, and for eradicating glandular enlargements, indurations, thickening of membranes and tumours, as well as in several other ailments. When applied to the skin, the cuticle becomes colored of an orange yellow, but this disappears after a short time. Iodine, in considerable doses, acts as an irritant poison, although to be fatal

Fig. 263.

longing to the right prismatic system. See Figs. 258, 259, 260, 261, 262, and 263. The finest crystals are obtained from its solution in ether, or one of hydriodic acid exposed to the air. By sublimation it is obtained in laminae, or broad oblique tables, which, when thin, transmit light of a red color, according to GMELIN; but PAYEN states that the crystals which form under the microscope, and do not exceed in thickness the two-thousandth of a millimetre, or .000787 of an inch, are without translucency. Iodine fuses at 224.6°, and boils between 347° and 356°, giving off violet vapors, which condense upon a cold surface, producing crystals. At ordinary temperatures it is subject to spontaneous

it must be exhibited in large quantities. In the event of poisoning by this element, the pump and copious libations of amylaceous liquids should be resorted to.

MANUFACTURE.—The atomic weight of iodine has been estimated by BERZELIUS as 126; its chemical symbol is I.

Iodine has been a subject of manufacturing industry almost from the time of its discovery; and the first to prepare it on the large scale was the discoverer, but more as a *dernier ressort*, than for the sake of the advantages which it then offered. It has been stated in the foregoing, that COURTOIS was actively engaged in the manufacture of saltpetre, in which business he had invested the whole of his money; but on the throwing open of the French ports for foreign products, immense quantities of nitrate of potassa arrived from India, which at once superseded the old nitre beds, and by so doing ruined COURTOIS. In this dilemma he tried to extricate himself by manufacturing iodine; but the consumption of the article being at this time very limited, and the process of its manufacture being circuitous, rendered the enterprise an unsuccessful one. It was prosecuted, however, after COURTOIS by MM. COURNERIE of Cherbourg, in the North-East of France, who are the oldest manufacturers after the discoverer. With its extended application, as well in medicine as in printing, and latterly in photography, others were induced to turn their attention to the subject, and now several manufacturers of the article may be found, among whom may be mentioned Mr. WHITELOW of Glasgow, and Mr. JOHN WARD of the county Donegal, Ireland.

The course pursued in its manufacture is simple. The several *fuci* and *algæ* which contain it, are collected by inhabitants of places adjacent to the sea-shore, and dried in the air, after which shallow rectangular

pits are dug wherein the dried material is burned. The semi-vitrified ash that remains is broken up by sprinkling a little water upon it whilst hot. This is the *kelp* of the Scotch and Irish, and is the same as the *varec* of the Continental producers; it is purchased by the several manufacturers, in order to extract from it the iodine and other salts. For this purpose it is reduced to a coarse powder, which is placed in rectangular filters, having an inner perforated bottom of sheet-iron. These are arranged two and two, to the number of six pairs, so that whilst the one is being filled, the other is working. Water is let in upon the powder at the furthest end, till it has risen a few inches above the solid matter; and after allowing it to remain for a short time, the tap in the false bottom is opened, and the liquor drawn off as it slowly percolates through the mass.

From the receptacle in which the solution collects, it is raised by means of a pump to the second pair of filters, where it is allowed to act upon the powdered material as in the preceding instance. In the same manner the lie which is run off from each pair of filters is pumped on to the next pair, the matter in which it partly exhausts; thence it is removed to the others, and so on, till it has traversed the entire range. The solution thus obtained has a density of 1.257, and contains, for the most part, chlorides of sodium and potassium, with the iodides and bromides of these alkalies. After drawing off this first solution, the washing of the residuary mass in the filters is continued, using only as much water for this purpose as will afford a lie of 1.145 density. This is added to the other liquor, and the whole is evaporated in a series of three boilers, so disposed that the cold liquor flows into the first of the series, thence to the second, and is

Fig. 264.

Fig. 265.

finally concentrated in the third, which is directly over the fire. Fig. 265 gives a longitudinal sectional view of the deposition of the evaporating pans, and Fig. 264 a transverse one.

In the former of these, the pans are indicated by A, B, C, E, and F, the latter being situated over the fire, D, the flue from which passes under each in succession. After the evaporation has reduced the liquid to a density of 60° Twaddell, or 1.30 specific gravity, the chloride of sodium and sulphate of soda crystallize out in the heat, and are separated by a ladle, and thrown into an inclined drainer, C—Fig. 264—the drainings returning to the pan. When no more salt is deposited at this density, the fire is slackened, and the contents of the boiler allowed to repose for some time previous to siphoning off into wooden crystallizers lined with lead. By this a further quantity of chloride is separated in the pan, and the sulphates which are still retained are deposited in the coolers as incrustations on the sides and bottom. After removing these, and permitting the menstruum to repose for some time

longer, a crop of crystals of chloride of potassium is obtained. The period allowed for the formation of the latter deposit extends to about five days, at the termination of which, the chloride of potassium is found in large crystals at the bottom of the vessel. The mother-liquor is again pumped back into the evaporators, and reduced to 68° Twaddell, at which degree, sulphate of soda, chloride of sodium, and carbonate of soda deposit. It is customary to add sulphuric acid to the liquid in the first stages, to neutralize the carbonate of soda; the quantity of the latter which the kelp affords—about two per cent.—being thought too small to be separated from the other salts. When this is done, only sulphate of soda and chloride of sodium separate after the second concentration. The crystalline mass is then removed, and the liquor left to part with a further quantity of chloride of potassium, as in the preceding case. At this stage the mother-liquor is retained for further treatment, which will be presently described. The semi-exhausted mass is again mixed with water fractionally, till the solution marks 1.073; and the men-

strum is treated in the same manner as the first, only in a separate set of evaporators. As this contains more alkaline sulphates than the forementioned, and less chlorides, the crystallizations are effected much more readily, and when brought to about the same degree of concentration, the mother-*lie*, after the crystals have been deposited, is added to that from the first affusions. Finally, the washings of the residuary

mass are continued till the whole of the soluble matters are removed; these weak solutions are advantageously used to exhaust fresh portions of the kelp.

The kelp may be economically edulcorated by an arrangement such as that represented in Fig. 266, in which the parts, A, B, C, D, and E, are a number of rectangular plate-iron boxes, placed in gradation one step above another. Only five are represented in the

figure, but, if need be, a greater number may be employed. The last of these vases is a cast-iron wagon of double the size of the others, at the level of the rim of which a cast-iron plate, K, is placed in an inclined position, so that any liquid falling upon it may flow into the tank. By means of a pipe connected with A, at about six inches from its bottom, and which rises to the level of the next vessel, the liquid in A may be drawn over into B, which is similarly connected with the next, C, and so on to the vat, F, which, also by means of stopcocks, yields its contents to a series of plate-iron pans placed in gradation, like the others. The kelp or varec to be exhausted is put in small pieces into baskets of plate-iron, perforated in the manner of a skimmer, which are then introduced into the vats filled with water, by two men, who lift them by a wooden pole which passes through rings in the rim of the cylinder. After remaining in the first vat for the space of half an hour, they are transferred to the next vat, and their place replenished with two others, charged with fresh material. The same process takes place every half hour till the top wagon, A, contains two pair, at which stage those which have remained in it during an hour are taken out, and placed upon the inclined plate, K, to drain. At each succeeding half hour the transferring and charging takes place as before, the exhausted matter in the drained hampers being carried to the waste-heap. From the time, however, that the latter takes place, a portion of water, about double the volume of the perforated cylinder, is drawn off from the lower, and its place supplied from the next above it; the others in succession borrow from their superiors to the top one, which is replenished with water from the tank pipe. In this way, rapid and perfect exhaustion is insured, whilst the liquor which is drawn from E to the *settlers*, F F, has always a uniform strength. After the matter which had been retained mechanically in the liquid has deposited in F F, the *lie* is drawn off to the first of the evaporating pans which have been already mentioned, for concentrating the solution, in order to remove the sulphates and chlorides contained in it before recovering the iodine. Sometimes at this stage, especially when the ebullition has been quickly carried on, the chlorides and other salts which separate are in such small crystals, that they pass through the skim-

mer, and cannot be removed from the solution; hence, when the alkaline salts in kelp are procured for useful applications, there is considerable difficulty in their subsequent purification, for the sulphates and chlorides deposit promiscuously in the crystallizing pans. In order to have the separation as perfect as possible, PAYEN recommends a boiler such as that depicted in the drawing—Fig. 267—and indicated by A, having a fire beneath at B, and at the side an inclined case, F, from which the crystals are permitted to drain into the pan. A hemispherical vessel, C, of plate-iron, perforated at the sides, and resting on the walls of the pan, A, is placed in the liquid when near the point of ebullition. This vessel can be lifted out when necessary, by means of a chain, passing over pulleys, and attached to the basin at one end by branching chains, the other

being equipoised by a weight. Ebullition of the contents of A soon takes place, and the liquid being put into violent commotion, carries the small crystals about; but as they gravitate, they fall in the centre, owing to the absence of an upward current, and are received in the vessel, C, in which they are easily removed.

Whatever course is pursued to separate the mother-liquor from the salts, it generally happens that, in addition to the alkaline iodides and bromides, sulphide of sodium, hyposulphite of soda, with notable quantities of chlorides, are present in the solution, and which, owing to their solubility, cannot be removed. To obtain the iodine, the Scotch manufacturers add to the liquid a seventh of its volume of strong sulphuric acid, specific gravity 1.845, and, having agitated the whole, leave it to repose from thirty-six to forty-eight hours. During this period the sulphurous compounds are decomposed, sulphates being produced, whilst sulphide of hydrogen and sulphurous acid pass off, and sulphur becomes precipitated. At the end of this time the

Fig. 267.

liquor is put into a retort which is adapted to a series of receivers, and heated to 140° . Having reached this temperature, a quantity of dry powdered binoxide of manganese is introduced through a tubulure in the head of the still, and the expulsion of the iodine effected at a temperature bordering on ebullition.

The chemical change which takes place in the course of the decomposition of the iodides by the sulphuric acid and binoxide of manganese, may be indicated thus:—

In this equation the oxygen from the manganese is represented as displacing the iodine, whilst the soda that is produced enters into combination with the sulphuric acid. Or it may be assumed that the binoxide of manganese, by acting upon the chlorides present under the influence of the excess of sulphuric acid, liberates chlorine, which in turn displaces the iodine thus:—

The distillatory apparatus employed is shown in Fig. 268, in which A is the still placed on an enclosed sand-bath over the fire, the door of which is shown at B. The head or capital of the retort is usually of lead, and is furnished with two apertures, *a* and *b*, which are closed

Fig. 268.

with stoppers. To the neck of the retort a series of spherical glass condensers, D D, are adapted, each of which has two apertures in its axis, one of which is drawn out so as to connect it to the next, as shown in the drawing.

After charging the retort, as already directed, with the liquor, and raising the temperature to about 140° , the peroxide of manganese is added in small portions through the stopper, *a*, and the temperature raised nearly to boiling; all the orifices and joinings being previously secured with the stoppers and pipe-clay, or other luting. The iodine passes over, and is collected in flakes in the receivers. The process is examined from time to time by opening the stopper *b*, and when the passage of iodine vapors slackens, more manganese—and acid, if necessary—are introduced through the stoppered aperture *a*, and the operation conducted till the whole of the iodine has separated. Such is the method pursued by Mr. WHITELOW of Glasgow, with this slight difference: he adds only an eighth part of sulphuric acid gradually to the liquor in a leaden boiler, and allows the sulphate of soda to crystallize out before introducing it into the still. It is important to retain the temperature at which the distillation proceeds at 212° , or nearly so, for above this the iodine is liable to pass over as chloride.

Sometimes, when the process is conducted in the manner just described, cyanide of iodine is produced, and is found in the third receiver in white needle-shaped crystals. The residue in the retort still retains some iodine in the form of iodide of lead and sodium. This can be recovered by the method proposed by SOUBEIRAN—namely, the addition of sulphate of copper, by which a subiodide of copper is formed. The precipitate is filtered, and the filtrate, which still retains some iodine, treated with a further quantity of the cupreous salt and iron filings, when another interchange takes place, and a further precipitation of iodide of copper occurs. The first of these changes may be expressed thus:—

And the second, by

The proper period for arresting the addition of the cupreous salt and filings in the latter case, is when the characteristic smell of iodine disappears. No time should be lost in removing the precipitate from the ferruginous salt and filings by washing and decanting from the fragments of iron, and subsequently filtering through a cloth. Both portions of iodine are desiccated at a gentle heat, and the dry compound mixed with twice or three times its weight of peroxide of manganese, and as much strong sulphuric acid as will form it into a paste, and the mixture strongly heated in a subliming apparatus, when iodine passes off and is received in appropriate vessels: thus—

The use of sulphuric acid may be dispensed with in

the above process, but the heat must be much more elevated when that agent is not employed. In this case, the binoxide of manganese is decomposed into sesquioxide of manganese and oxygen, which displaces the iodine combined with the copper, as shown in the annexed equation:—

According to SOUBEIRAN, this method is very economical, and affords as much as one per cent. of the mother-liquor operated upon.

At the Cherbourg Works the mother-waters are treated in slight excess with sulphuric acid, and the solution is afterwards boiled for some time; during this operation the sulphides, hyposulphites, and sulphites are decomposed, sulphurous acid, *et cetera*, being eliminated, and sulphur precipitated. Some time is now allowed, in order that the solution may clarify, and when this is effected, the supernatant fluid is drawn off from the precipitate and diluted till it marks 40° Twaddell, and then chlorine passed into it to saturation from a generating apparatus, such as that shown in Fig. 269. The chlorine passes off from the stills, A, B, where bin-

Fig. 269.

oxide of manganese and hydrochloric acid are made to act upon one another, or chloride of sodium, sulphuric acid, and binoxide of manganese, and proceeds by the conduit, E; into the vat, where it liberates the iodine from its combination in the mother-liquor. The end of this operation is the decomposition of the iodide present, or rather of the hydriodic acid, and the evolution of the iodine by the substitution of the chlorine; the iodine, being only slightly soluble, precipitates. In transmitting the chlorine through the liquid, it is necessary to guard against two evils: the first arising from the use of this agent in insufficient quantity, for in this case the iodine compound remains in part undecomposed; the second, produced by an excess of the gas, owing to the formation of chloride of iodine, which passes off in vapor, and is lost. Hence, to determine the exact point, it is necessary to test a part of the liquid as well with chlorine as with a solution of iodide of potassium, to prove, on the one hand, if there remains any further portion of the salt unacted upon; and on the other, if the agent be present in excess. Should the latter be the case, a further addition of mother-liquor is made to combine with the free chlorine. When the decomposition is complete, the contents of the vessel are allowed to settle, and after a time the clear liquor containing chlorides and sulphates is drawn off from the iodine. The latter is repeatedly washed by decantation, till the washing gives no indication by the hydrometer of the

presence of salts. The iodine is afterwards put and left to drain in a conical vase of pottery-ware, the bottom of which is perforated and rests upon a jar of freestone; it is then dried upon sheets of filtering-paper laid upon well-dried cinders, or upon porous tiles.

Fig. 270

The next step is the purification by a process of sublimation in an apparatus like that shown in Fig. 270. The iodine is introduced into the retorts, A A, which form a gallery of two rows, to the number of six; they are immersed in the sand of the cast-iron case, B B, which is heated by the fire, C. Into each of these about forty-five pounds of the crude iodine are introduced; they are then wholly buried in the sand, the neck as well as the body of the retort. This precaution seems necessary, to prevent the condensation of the iodine vapors in the neck, and the obstruction of the passage which would ensue. That this may be guarded against as much as possible, the necks of the retorts are short, and the receivers placed in connection with them as close to the sand-bath as possible. An elliptical cistern, D D, is used for this purpose, the beak of the retort entering at the side. It is furnished with a movable cover, E, to facilitate the removal of the iodine; it has likewise a perforated plate at the bottom, H, to allow any water which may condense to drain off. A tubulure, F, at the opposite side to that which receives the beak of the retort, allows the vapor of water to pass off by the pipe, F G, out of the range of the operation. In this way the iodine is obtained in fine large crystals.

When the bromine which is present is to be recovered, the liquor drawn off from the precipitate is evaporated to dryness, the residue compounded with sulphuric acid and binoxide of manganese, and distilled from a leaden vessel. Bromine passes over, and is received in strong sulphuric acid, in which it sinks, and is thus prevented from fuming, and injuring the health of the workmen.

IMPROVED PROCESSES.—BARRUEL'S process resembles the last in some of its operations. The remaining mother-liquor is evaporated to dryness, the residue mixed with about one-tenth of its weight of binoxide of manganese, and then heated to about incipient redness, the mixture being kept stirred all the time. The heat is continued till the sulphides and hyposulphites

are thoroughly oxidised, which is known by treating a sample of the substance with sulphuric acid, and observing if sulphide of hydrogen be evolved. In this operation the heat should not be raised to such a degree as would cause the evolution of iodine, of which the characteristic violet vapor would be an indication. Water is added to the mass, and the sulphates and iodide of sodium are washed out; using only as much water, however, as will afford a solution of 36° Beaumé. Chlorine gas is now passed through the filtrate, and the iodine which is precipitated purified, as described in the preceding method.

In order to avoid the loss of iodine consequent upon the burning of the plants for the production of kelp, Dr. KEMP suggests a method whereby the iodine may be extracted, and the burning—as in the production of kelp, by which, doubtless, much iodine is dispersed—dispensed with. His suggestion is to crush the roots which contain the largest proportion of iodine, and to set them by in a heap, tank, or any convenient vessels, for a few days, and after the fermentation which ensues has subsided, to extract the soluble salts, among which will be the chief portion of the iodides, with cold water slightly acidulated with ordinary hydrochloric acid. This liquid is to be then treated with chloroxide of calcium—bleaching powder—in slight excess, so as to liberate the iodine, and the latter precipitated by adding to the liquid a sufficient quantity of amidacetate of lead—prepared by adding a solution of tribasic acetate of lead to well-washed potato starch—by which the whole of the iodine is carried down. The precipitate may be washed and dried, and in the hands of the manufacturer the iodine may be removed from it by adding a solution of sulphide of potassium, which precipitates sulphide of lead, leaving iodide of potassium in the liquid. After filtration the liquid may be concentrated, and the iodine extracted by one or other of the processes mentioned. The fluids from which the precipitated compound of iodine and amidacetate of lead is separated, may be useful in an agricultural point of view, either for mixing in the compost heap, or with other liquids in the manure tank. The cakes of cellular tissue which result from the pressure of the material after fermentation, may be dried and used as fuel; the ashes being preserved, on account of the portion of iodine they still retain, as well as for the other salts, which are valuable, both in an agricultural and manufacturing point of view.

Professor BECHI has indicated a process by which iodine may be economically obtained from river and other waters containing it in small proportion. His method of procedure is, to treat the waters with a mixture of one part of sulphuric acid and two of nitric, and to pass the acidulated liquor into a tank or vat, having a funnel-shaped bottom, and filled with lamp-black that has been heated to redness, or well-made ivory-black. The acids have the effect of removing the bases from the iodine, and on transmitting the solution through the charcoal, the latter is retained. When the lamp-black is charged with the iodine, and it is desired to obtain it, a solution of potassa is added, or what is better, the carbonaceous matter is mixed with hydrated protoxide of iron in a tub. After a

while the iodine is taken up, and an iodide of potassium or of iron produced. When the action has been sufficiently completed, water is allowed to flow upon the mass to dissolve these salts, the solution being drained off in another funnel-shaped vessel, which is stopped in the tube part with sponge or other porous material. The liquor is evaporated to dryness; and, in case of potassa being used, the iodide and iodate are decomposed by sulphuric acid and binoxide of manganese in the manner described in the foregoing. The iodide of iron may be operated upon in the same way; or, if it be thought better to dispense with the evaporations, a sulphate of copper solution may be added, and the precipitate of subiodide of copper, which falls after filtration and washing, distilled with sulphuric acid and binoxide of manganese, *et cetera*.

In a paper by SCHÖNBEIN—see *Chemical Gazette*, vol. viii., p. 166—several substances are described which are able to decompose the alkaline iodides, so as to liberate the non-metallic element in the dry way. Such are the metallic oxides and acids, containing two, three, and five equivalents of oxygen; but many seem to exercise an unequal degree of power in effecting this change. The most remarkable are arsenious acid, chromic acid, sesquioxide of iron, and protoxide of copper; but there is danger in employing the first of these, lest a portion of the poison might be driven off by an increased temperature with the iodine, and thus render its application dangerous as a therapeutic agent. When three parts of bichromate of potassa are ground and mixed with two of iodide of potassium, and the mixture is submitted to dry distillation in a stoneware retort, the whole of the iodine is set free, leaving in the vessel a greenish mass, which is a mixture of chromate of potassa and sesquioxide of chromium. The decomposition is represented by the following equation:—

The iodine which is thus produced is very pure, and no loss either of it or the reagent is experienced; for the chromate, which is a residuary product of the distillation, is a valuable salt, and applicable for many purposes; whilst the green sesquioxide left after washing away the former, may be employed as a pigment in painting upon porcelain, *et cetera*; or by fusing it with an alkaline nitrate and carbonate, it may be reconverted into a bichromate of the alkali, which may be employed to decompose a fresh portion of iodide.

Iodine is also set free when anhydrous sesquichloride of iron is mixed with iodide of potassium, even at ordinary temperatures; and, on the application of heat, it passes off in dense vapors, which may be received in the usual manner. The change of the substances in this instance is due to the reduction of the ferruginous sesquisalt to that of a protosalt; the liberated equivalent of chlorine assimilating with the potassium, and thus setting the iodine free:—

Sesquisulphate of iron may be advantageously substituted for the preceding salt; for, when an alkaline iodide is moderately heated with it, dense vapors of iodine are liberated, quite free from sulphurous acid or other impregnation. Hence, by employing sesquioxide of iron and iodide of potassium in equivalent proportions, and adding to the mixture three equivalents of sulphuric acid, so diluted as not to be able by itself to liberate iodine, then moderately heating—the whole of the iodine passes over into the receiver, and the residuary matter is composed only of sulphates of potassa and of iron, as may be seen by the subjoined formula representing the interchange which takes place:—

COMBINATIONS OF IODINE.—Allusion has already been made to the compounds which iodine forms with some of the other elements; and a short description of the more important and useful products formed by combining this element with others, both of a metallic and non-metallic nature, will now be given.

All the non-metallic elementary bodies, with the exception of fluorine, are capable of entering into combination with iodine, either in single or multiple proportions, and many of these compounds are so persistent as to offer considerable resistance to opposing affinities before being resolved into their elements. Like chlorine, sulphur, phosphorus, *et cetera*, iodine constitutes with hydrogen and oxygen acid compounds which, in their general characteristics, are analogous in every respect. With nitrogen and ammonia it affords a compound which is eminently explosive, but with the other simple bodies its combinations offer little interest beyond the precincts of the laboratory. Many of its compounds with the metals are very valuable, as well in medicine as in many branches of industrial art; and to the chemist they are in frequent demand as effective reagents both for ascertaining the presence and estimating the proportion of numerous bodies. Of these, however, reference will be made only to those of alkali metals, iron, silver, mercury, and a few others.

IODIDE OF HYDROGEN—Hydriodic Acid—Iodhydric Acid.—Next to oxygen, chlorine, bromine, and fluorine, iodine manifests the greatest affinity for hydrogen; consequently, it abstracts this element from its combinations of phosphide of hydrogen, sulphide of hydrogen, ammonia, as well as from alcohol, ether, and volatile oils; in each instance hydriodic acid results. A similar metamorphosis with regard to the iodine takes place when it is mixed with water in the presence of a body capable of abstracting oxygen from the latter; and by this means hydriodic acid is sometimes prepared. Thus, when a mixture of nine parts of iodine and one of phosphorus is introduced into a tube,

VOL. II.

A—Fig. 271—and covered with moist quartz, sand, or powdered glass, and heat applied, decomposition of iodide of phosphorus, which is at first formed, takes place, as it comes in contact with the thin stratum of moisture, and hydriodic and phosphorous acid are produced; the former being volatile, may be conducted by

Fig. 271.

a tube, B, to the receiver, C, in which it may be collected. The change of elements in the reaction alluded to may be expressed thus:—

Only a slight heat should be applied to produce this decomposition, for, if the temperature be elevated, some terhydride of phosphorus is apt to form and pass over into the receiver, and contaminate the hydriodic acid. Another method is to compound one part of phosphorus, fourteen of iodide of potassium, and twenty of iodine, with a little water, and submit the mixture to heat in a retort or distillatory vessel fitted up on the principle of the apparatus in the preceding figure. When the evolution in this case becomes too rapid, the retort should be cooled by plunging it in cold water; and, on the other hand, when it slackens, the heat must be reapplied.

Several modes may be adopted for preparing this acid in the liquid state: thus, iodide of barium or of lead may be decomposed by an equivalent proportion of sulphuric acid, and the liquid, after filtering off the insoluble precipitate of sulphate of baryta or of lead, concentrated; this product will be aqueous hydriodic acid. Iodine is diffused in water, and sulphide of hydrogen transmitted through it, when decomposition of the latter takes place, sulphur being precipitated, and hydriodic acid produced. A difficulty is, however, experienced in this process, notwithstanding its being effectual—namely, the evisceration of a portion of iodine by the depositing sulphur, by which the whole of the former cannot be conveniently transformed in its hydracid. DUMAS proposes to remedy this defect by merely saturating a given volume of water with iodine, and, after allowing the insoluble portion to subside, and decanting the brownish fluid, he directs that the sulphide of hydrogen should be passed through it till it becomes colorless. The deposited sulphur is then filtered, and the filtrate again charged with the iodine, and the portion which dissolves again acted upon as before. In this way the whole of the iodine may be

3 D

converted into the acid; for at each succeeding saturation, in consequence of the portion of hydriodic acid that is formed, the liquid acquires the property of dissolving a larger quantity of the iodine. The process is troublesome, however, from the repeated filtrations and solutions. Hydriodic acid might be obtained with considerable facility by passing the gas through a solution of iodine in alcohol, were it not that some sulphide of carbon would be produced by the action of the sulphur on the spirit, and which could not be conveniently removed.

Hydriodic acid, prepared according to the first of these methods, is a colorless gas, soluble in water, and capable of strongly reddening litmus; it has an acerb taste and very pungent odor, somewhat similar to hydrochloric acid. When allowed to escape into the air, it produces dense white vapors, which are very suffocating when inhaled. Its density is 4.3757, according to THOMSON, but GAY-LUSSAC gives it 4.4429, air being taken as unity; it is neither a combustible body nor a supporter of combustion. Steam, sulphurous acid, chlorine, bromine, and a few other bodies, are capable of decomposing hydriodic acid with the separation of iodine in every instance. The gas is composed of half a volume of iodine and half a volume of hydrogen. In the liquid state hydriodic acid is colorless, and of a specific gravity 1.700. It is highly acid, and possesses an odor similar to that of the gas. Upon exposure it gradually suffers decomposition, being converted into hydriodous acid with the evolution of hydrogen; but, with prolonged contact with the air, the oxidised portion reacts upon the remainder, and causes the liberation of the iodine, which separates in fine lamellar crystals.

Sulphuric acid, when concentrated, sets free the iodine, a portion of the agent being at the same time broken up into sulphurous acid and oxygen. Hydriodic acid has been solidified by FARADAY at a temperature of -59.8° Fahr. In this state it is perfectly transparent and colorless, but intersected with fissures like ice. The tension of the vapor at 0° is 2.9 atmospheres.

This acid is capable of decomposing the oxides of most of the metals affording metallic iodides and water. Its symbol is HI, and its atomic weight 127.

Iodine forms, with oxygen, compounds of various degrees of oxidation, the lowest being iodic oxide— IO , and iodous acid— IO_2 ; the highest iodic acid— IO_3 , and periodic acid— IO_4 . The latter three constitute salts with the metallic bases, which are called iodites, iodates, and hyperiodates respectively. To enter into a description of the processes by which they are prepared, would not be warranted by the uses which they serve—namely, of forming the links of analogy between iodine and chlorine, bromine, *et cetera*.

With sulphur, phosphorus, chlorine, and bromine, it produces several compounds, which are very interesting to the chemical student. The combination of iodine with nitrogen is remarkable, in being analogous to the chloride of this element, although the explosion which it produces is much less violent.

Iodide of Nitrogen.—If dry iodine and ammonia are brought together in close vessels, they form a brownish liquid, which is simply a combination of the two sub-

stances, and which may be represented by the formula $3(\text{NH}_3) \text{I}_2$. When, however, the iodine is digested with a strong solution of pure ammonia, the compound in question falls as a black powder. The same change takes place when carbonate of ammonia is substituted for the caustic alkali, or chloride of iodine for the pure element. To favor the reaction in this case, the mixture of the ingredients should be effected with a gentle abrasion in a mortar. The powder should be washed on a filter with water, to remove the excess of ammonia and the iodide of ammonium which forms. Another method for preparing the compound with equal facility, but without incurring the risk of spontaneous explosion, is to dissolve the iodine in alcohol 54.5° Twaddell, and, after decanting the tincture, saturating it with a strong solution of caustic ammonia. After briskly agitating, the mixture is diluted with water upon which the iodide of nitrogen precipitates, and may be washed in the cold with this liquid either by subsidence and decantation, or on the filter. The iodide thus produced is not spontaneously decomposed; but SERULLAS remarks, that if the iodine be precipitated from the alcoholic solution by water, and the solid thus recovered treated with ammonia, a compound results which is very apt to explode even during the preparation. Subsequently to the affusion, the compound is dried carefully upon bibulous paper at the ordinary temperature. In performing this operation, care should be taken to divide the mass into small portions, which ought to be placed at a distance from one another, in order to preclude the possibility of an explosion of any considerable quantities of the salt.

MILLON states that it may be desiccated with safety in a bell surcharged with ammoniacal gas, and no decomposition occurs even after lengthened exposure, provided the atmosphere is one of ammonia.

The slightest cause is adequate to decompose the iodide of nitrogen with a violent explosion, and the evolution of a violet light which is visible in the dark. The feather of a quill drawn over the powder is sufficient to produce this effect, and if contained in a dish in moderate quantity, the force is such as to shatter it in pieces. Even if rubbed strongly under water, an explosion takes place; but the causes which determine this change in the air are incapable to effect the decomposition when it is mixed with large quantities of water. It is not liable to explode by mere contact with oils and fats, like the chloride of nitrogen. The products of the decomposition of this peculiar salt, so far as they have been examined, seem to be pure nitrogen, finely divided iodine, and hydriodic acid; but some assert that iodide of ammonium is produced. MARCHAND found that traces of the latter salt were formed upon the sides of a glass jar, in which portions of the nitrogenous compounds had been successively exploded. Water gradually dissolves the iodide of nitrogen with the formation of iodide and iodate of ammonia, free iodine, and the evolution of small quantities of nitrogen. By the action of heat, or sulphuric or nitric acid, the action is considerably expedited. Sulphide of hydrogen effects an immediate decomposition of this compound, the products being iodide of ammonium, hydriodic acid, and sulphur; the alkalies, lime, *et cetera*, operate in a

similar way with the liberation of ammonia, and the formation of an alkaline iodide and iodate.

Composition of Iodide of Nitrogen.—The composition of this body is as yet somewhat doubtful, being regarded in the several lights of iodide of nitrogen— NI_3 , iodide of amidogen— NH_2I , or as a mixture of the former of these with an equivalent of ammonia. The following are the data furnished by the calculations of the investigators whose names are attached:—

GAY-LUSSAC.

A.		Centesimally.	
1 Eq. of Nitrogen.....	14	=	3·57
3 Eqs. of Iodine.....	378	=	96·43
	392	=	100·00

1 Eq. of Nitrogen.....	14	=	10
1 Eq. of Iodine.....	126	=	90
	140	=	100

MILLON.

1 Eq. of Amidogen	{ 1 Eq. N = 14	=	986
	{ 2 Eqs. H = 2	=	1·41
1 Eq. of Iodine	= 126	=	88·73
	142	=	100·00

According to the recent analysis of BUNSEN, however, it appears that the composition of the compound is NI_3 , NH_3 , but that another compound of these elements exists, presenting the composition indicated by the formula $4(\text{NI}_3)$, NH_3 , and which results from the precipitation of an aqueous solution of chloride of iodine by ammonia. In either case he regards these iodides as ammonia compounds, in which the hydrogen is entirely replaced by iodine, and which unite with an equivalent of undecomposed ammonia, as expressed by the formulæ. He gives the equation representing the formation of this explosive body by the mutual action of iodine and ammonia, thus—

And by the effects of ammonia upon chloride of iodine, thus—

Combination of Iodine with Metals.—With most of the metals iodine enters into combination, producing metallic iodides, but, in forming such, very diverse phenomena are exhibited; some are produced instantaneously, on account of the force of the affinity which exists between the elements, whilst others require very careful and circuitous manipulations, in order to effect the union of both substances.

Only a few of these combinations have been brought into use in the arts and sciences, consequently it will be unnecessary to pursue their description beyond those compounds which are available in medicine, photography, *et cetera*. Such are the alkaline iodides, iodides of iron, of mercury, and of silver, with a few others.

Iodide of Ammonia.—When dry ammoniacal gas and iodine are brought in contact, combination takes place, and a heavy blackish-brown, very tenacious

liquid is produced; the same compound is obtained on gently heating equal weights of sesquicarbonate of ammonia and iodine in a retort or porcelain tube, water and carbonic acid being formed. The change may be expressed thus—

The compound is easily decomposed in part when heated, ammonia being set free; the chief portion of the iodine salt, however, sublimes in violet-colored vapors. It indicates the presence of ammonia and iodine. Its composition, according to MILLON and BINEAU, is—

MILLON.

	At. weight.	Centesimally.

Iodide of Ammonium.—The compound which is met with in commerce, and intended chiefly for the photographer, is prepared by neutralizing a solution of ammonia with hydriodic acid gas, and subsequently decomposing any iodate of the alkali, by transmitting a slight excess of sulphide of hydrogen through the liquid, evaporating the liquor in a water-bath, and afterwards filtering off any deposited sulphur. When the evaporation is conducted carefully under the bell jar of an air-pump, the salt crystallizes in cubes and is colorless; but if exposed to the air, it readily deliquesces, and turns brown, owing to a portion of the iodine being set free. It may be prepared likewise by bringing ammoniacal and hydriodic acid gases in contact, or by decomposing iodide of iron by carbonate of ammonia, filtering off the ferruginous precipitate, and evaporating the solution till the iodide crystallizes.

The iodide of ammonium thus prepared is a very deliquescent salt, very soluble in water and alcohol. By keeping, even in diffused daylight when out of contact with air, it decomposes, turning brownish-yellow, ammonia being evolved. It may be represented as NH_4I , or NH_3HI , and its per centage composition as—

	At. weight.	Per cent.
1 Eq. of Ammonium,.....	18	= 12·50
1 Eq. of Iodine,.....	126	= 87·50
NH_4I ,.....	144	= 100·00

Iodide of Potassium.—This salt is one of the most valuable compounds of iodine; its importance is derived from its medicinal effects chiefly; but as a reagent in the laboratory and in photography it is, especially for the latter, in general use. There are several recipes for preparing it, the most appropriate of which will be here noticed.

When potassium and iodine, or iodine vapor, are

brought together, rapid combination takes place with a considerable rise of temperature, and the evolution of a violet light. If the combination be aided by heat, the union of the two elements is often attended with a violent explosion. The result is iodide of potassium.

To prepare this body with materials which are more easily obtained, and at less expense and trouble than potassium, other processes are adopted. The simplest of these appears to be the following:—Powdered iodine is agitated with a solution of caustic potassa as long as the former dissolves. Its point of saturation is known by the liquid acquiring a brownish tint. When this happens, any excess of iodine is removed by subsidence and decantation of the liquor, or it is acted upon by a proportionate quantity of the alkaline lie. By evaporation there is obtained a white residuary mass, consisting of iodide and iodate; the latter is decomposed by heating the mass gently for some time, when iodide of potassium only remains. There is need, however, of giving particular attention to this part of the operation; for if the temperature be too elevated, some loss of iodide of potassium by volatilization is sustained; and, on the other hand, if too low, portions of iodate remain undecomposed and contaminate the salt. To avoid this, ORFILA, and latterly SCANLAN, recommend to mix the dry residue with charcoal-powder before submitting it to the action of the heat; this has the effect of bringing about a more perfect decomposition, and at a lower temperature, than could be effected without it. No iodine is liberated, and the whole of the oxygen of the iodate is taken up by the carbon, which is thereby converted into carbonic acid. After heating, the mass is exhausted with water, which dissolves out the iodide. Alcohol may be substituted with advantage when a very pure product is desired, for this takes up only the iodide and leaves the carbonate of potassa, which is nearly always present. By distillation the spirit may be removed, and the iodide crystallized from the concentrated alcoholic solution, or from water. If the residue, after the first evaporation, be treated with alcohol only, the iodide of potassium dissolves, the iodate and any carbonate which might have been present in the alkaline liquor remaining behind. This residuary salt may be afterwards heated with charcoal, and the iodide to which it is reduced extracted as above. In both cases the changes which occur may be thus symbolized:—

the final product by the application of the heat becoming iodide of potassium, thus:—

The method of saturating a solution of potassa, or of carbonate of potassa, with hydriodic acid, offers very good results, were it not that the preliminary operation involved in the preparation of the hydriodic acid renders the course rather circuitous. By forming an iodide of zinc, as recommended by LE ROYER and DUMAS, the operation is shortened and simplified. Zinc turnings, water, and iodine are agitated together in a close vessel, and the metallic salt which is thus produced is afterwards decomposed by addition of carbonate of potassa

to the liquid as long as a precipitate appears. The carbonate of zinc is filtered, and the solution evaporated to the crystallizing point. This method is objected to on account of the difficulty which is experienced in removing the last traces of iodide of zinc. In order to obtain a pure salt by this process, GIRAULT gradually pours the cold solution of the iodide of zinc into a boiling hot one of carbonate of potassa as long as there is any effervescence observed; cold water is then added to the mixture, and the whole filtered, and the carbonate of zinc washed twice with water. The trace of zinc still held in solution is removed by the cautious addition of carbonate of potassa, the precipitate filtered, and the liquid concentrated and set by to crystallize. By many iron is substituted for the zinc, but the further steps in the process are decidedly the same. Two parts of iodine, one of iron, and ten of water are agitated together in a close vessel till the liquid loses its brown color; as soon as this happens, the liquid is filtered, and precipitated by a solution of caustic or of carbonate of potassa heated to the seething point. Care must be taken that the air is as much as possible excluded during the production of the iodide of iron, so as to prevent the formation of a basic iodide of this metal, which could be decomposed only by an excess of alkali.

The Dublin college directs the conversion of the iodine into hydriodic acid by sulphide of hydrogen, and the neutralization of this product either by potassa or carbonate of this alkali. TADDIE employs an alcoholic solution of iodine, or iodine diffused in water, and adds to it an aqueous or alcoholic solution of sulphide of potassium till the whole becomes colorless. Sulphur which separates in this operation is removed by filtration, and the liquid evaporated to obtain the salt in a crystalline state. It may be observed that in this process, when alcohol is employed, the iodide of potassium is always more or less of a brown color. Further, when the sulphide of potassium is present in excess the liquid becomes cloudy, to remove which a greater quantity of iodine must be added. Notwithstanding these precautions, it appears, that the iodide of the alkali produced is, to some extent, impregnated with sulphur; for upon heating, it turns grey, and evolves sulphide of hydrogen. The process recommended by STEPHANI is merely the old one of TURNER, mentioned above, modified. Into a bath of the caustic alkali, iodine is introduced in small portions at a time until the liquid begins to be tinged. The weight of iodine necessary to effect this is found by having a determined quantity of iodine to begin with, and weighing what remains. After the point of incipient coloration is observed, as much more iodine as is already contained in the liquid is to be added, and the whole agitated until it dissolves. Iodide of potassium and iodate of potassa are thus produced, and by treating the liquor with sulphide of sodium, prepared by saturating a solution of an equal quantity of alkali to that to which the iodine was added with sulphide of hydrogen; both liquors are mixed and left to repose, when, by mutual decomposition, the contents of the vessel become muddy in consequence of the deposition of sulphur; after a short interval this sulphur falls to the bottom, when the whole is passed through a filter, and the percolating liquid concentrated so as to obtain the salt.

STEPHANI states that very beautiful transparent crystals are obtained in this way, and which are quite different in this respect from the salt met with in the market.

Iodide of potassium crystallizes from its aqueous solution in the form of cubes, parallelopipeds, pyramids, or octahedrons; and, according to KANE, sometimes in forms belonging to the square prismatic system. The crystals are soluble in about three-fourths of their weight of water at ordinary temperatures, and in six parts of alcohol of 0·85 specific gravity. By this solution in water the temperature is reduced about 75·2°. The boiling point of the saturated solution is about 248°. The salt melts at a temperature below redness, and forms pearly crystals on cooling; if air be admitted to it whilst in a state of fusion, a portion volatilizes undecomposed. SCHINDLER found, when performing the experiment in glass tubes, that the volatilization does not take place below the fusing point of the glass. Chlorine, sulphurous acid, sulphuric and nitric acids, are capable of decomposing iodide of potassium, yielding iodine in the free state; or, in the case of sulphuric acid when diluted, hydriodic acid, as noticed under the manufacture of iodine. According to GAY-LUSSAC, it may be represented by KI, being composed of—

		Centesimally.
1 Eq. of Potassium,.....	39	= 23·63
1 Eq. of Iodine,.....	126	= 76·37
1 Eq. of Iodide of potassium,...	165	= 100·00

The iodide of potassium is liable to much adulteration, as well from the nature of the processes followed in its manufacture, as from intentional additions of other bodies of less value. Those bodies, the presence of which is consequent upon the method of manufacture, are carbonate of potassa, chloride of potassium, sulphate of potassa, iodate of potassa, and, under particular circumstances, traces of a substance known as xanthate of potassa. Carbonate of potassa, derived from the imperfect neutralization of the iodide or hydriodic acid, in the first instance, may be discovered by the effervescence which succeeds the addition of hydrochloric acid to a portion of the salt, and also by its solution giving a precipitate with lime water; this impurity remains undissolved when the salt is treated with alcohol. Traces of alkaline chlorides may be derived from its being contained in the alkali taken to prepare the salt. Their presence is detected by its giving a precipitate with nitrate of silver, which is soluble in ammonia, and is reprecipitated from this solvent in the state of white chloride of silver by nitric or sulphuric acids. Sulphuric acid is detected by adding to a weak acid solution a few drops of chloride of barium. Alkaline sulphates are also left undissolved when a portion of the sample is treated with alcohol. Xanthate of potassa is produced when the iodide is prepared by the action of sulphide of potassium or of barium upon iodine dissolved in alcohol. When this body is present, the taste of the salt is like that of asafetida; it turns greyish-brown on being heated, and evolves sulphurous acid; when the heated residue is treated with water, a substance remains undissolved

which is composed chiefly of carbon, but traces of sulphates are found in the solution. Iodate of potassa is detected by adding a weak acid, by which hydriodic acid is liberated; this effected, the liberated hydracid exercises a deoxidizing effect upon the iodate, its hydrogen combining with the oxygen of the iodic acid of the latter, and setting the iodine free. Thus—

Such disengagement of iodine is indicative of the presence, not only of an iodate, but likewise of any other of the higher oxygen acids. Exclusive of the substances mentioned, and which are never contained in greater proportion than one to two per cent., adulteration of this salt has been known and detected to the extent of seventy and eighty per cent.

Besides the process, which will be detailed at the end of this article, for the analysis and determination of iodine, as well in the commercial article as in the iodides of the metals, a simple process, applicable for the estimation of the amount of iodide in the alkaline salts, may be here mentioned. It is founded upon the behavior of the alkaline iodides with chloride of mercury, whereby an equivalent of either the potassium or sodium salt precipitates exactly an equivalent of chloride of mercury in the form of iodide. The insoluble compound thus formed is, however, redissolved by a second equivalent of the alkaline salt, in consequence of the production of a soluble double iodide of mercury and potassium. The reactions may be expressed thus:—

And secondly—

To test the salt, two equivalents—330 parts—and one equivalent of chloride of mercury—135·5 parts—or any less weight of each, provided this ratio is retained, are weighed and dissolved in equal measures of water, say one thousand grains. To the solution of the iodide the mercurial liquor is to be added till a permanent precipitate appears. Should it happen that no turbidness arises, even when the whole of the latter liquor has been added, it is a proof that no adulterant exists in it; but if a precipitate should occur when only the one-half or one-fourth of the mercurial liquor has been poured in, it is evident that the iodide must be adulterated with one-half or one-fourth of some spurious matter. When iodide of sodium is to be tested in this way, it will be clear that the weight of the salt to be taken will differ from that specified for the potassium salt, in proportion as its equivalent weight is less; that is, only two hundred and ninety-eight grains are required.

Iodide of potassium is used in the laboratory as an agent for producing metallic iodides, and by the photographers largely, in preparing the silver baths wherein the plates are immersed; its chief application

is in the latter art, and in medicine. Its medicinal properties are, in a great measure, similar to those of iodine itself. For further information on its physiological properties, the reader is recommended to consult the able work of the late Dr. PEREIRA.

Iodide of Sodium.—The description given for the obtaining of the preceding iodide will fully answer for the manufacture of this compound. The crystals, however, retain four equivalents of water when they form in an aqueous solution of the salt; they are larger than those of iodide of potassium, and present the appearance of oblique rhombic prisms; they melt in their water of crystallization when heated, giving the anhydrous salt; if the temperature be maintained, they dissolve in 0.6 parts of cold water. According to MITSCHERLICH, it is composed of—

		Centesimally.	
		Theory.	Mitscherlich.
1 Eq. of Iodide of sodium	= 149	= 80.21	= 80.6
4 Eqs. of Water	= 36	= 19.79	= 19.4
	182	100.00	100.0

Symbol, Na I, 4 HO.

Iodide of Iron.—This salt, as already intimated, is prepared by agitating water and iron turnings, or fine wire, and iodine together, taking the precaution to retain the presence of an excess of the metal. The iodine attacks the metal, and combines with it, forming a soluble iodide of iron. The compound, though readily prepared in the state of solution, is more difficult to obtain as a solid, owing to its tendency to decompose, yielding free iodine and a basic iodide, which is but sparingly soluble. During the concentration of the solution of iodide of iron this change occurs, unless it be guarded against by the evaporation being conducted in an iron vessel, or in contact with iron wire, which prevents the oxidation of that portion of the salt which is already formed. Carefully concentrated thus, the compound may be obtained, on cooling, in the state of a crystalline mass; but in this condition it cannot be long preserved, especially when air has contact with it, iodine being set free, as just indicated, and an oxide of iron mixed with iodide remaining. This salt is of no very great importance; it is sometimes employed in medicine, with other substances; it is also occasionally used as a photographic agent. Its symbol is Fe I, and the atomic weight, 154.

Iodide of Mercury.—Mercury is capable of forming several combinations with iodine, but that which will be noticed more particularly here, is the iodide or protiodide of the metal. If two equivalents of mercury and one of iodine are triturated together in a convenient vessel, moistening the whole with alcohol, a subiodide of mercury is obtained in the form of a greenish powder; the same compound is formed when a solution of subnitrate of mercury is precipitated with one of iodide of potassium. The resulting mass is composed according to the formula $Hg_2 I$.

If iodine be added to the solution of iodide of potassium, and the brownish liquid which results be mixed with a solution of subnitrate of mercury, a precipitate falls which differs in composition from the foregoing. It may also be procured by adding the iodide of potassium

to an acid solution of the mercurial salt, but the first is the surer method. It forms a yellow powder, which is apt to vary in its composition, according to the conditions in which the two salts are brought together. When treated with an acid, a red salt—the iodide—deposits. According to BOULLAY, this compound is composed of four equivalents of mercury and three of iodine, and is represented by the symbol $Hg_4 I_3$. The most remarkable of the mercurial compounds with iodine, owing to its fine scarlet hue, is that which is thrown down when dissolved chloride of mercury—corrosive sublimate, $Hg Cl$ —is added to iodide of potassium. If the iodide of potassium has been added only sparingly, the tinge will be duller, in consequence of a portion of chloride of mercury being carried down; on addition of a further quantity of the reagent, however, this is displaced, and the whole of the quicksilver is converted into the brilliant-colored precipitate. The operator should guard against the opposite extreme of using too great an excess of the iodide, which would have the effect of redissolving it, and producing a soluble double iodide of mercury and of potassium.

The red iodide of mercury may likewise be obtained by triturating iodine and the metal together in the ratio of their equivalents, alcohol being added. This, however, should be done with only small portions at a time, for, when large quantities are operated upon, the temperature becomes so elevated as to volatilize much of the iodine. A duller-tinted compound is produced in this way, than that which results from precipitation with iodide of potassium or hydriodic acid.

When the iodide of mercury thus prepared is heated, it fuses, and a dark yellow mass remains, which, on solidifying, retains the yellow hue. As the temperature lowers, however, the original color is regained. The composition in both cases remains unaltered, consequently the dimorphous effect must be attributed to a molecular arrangement which is produced by the increased heat. Iodide of mercury is slightly soluble in water, alcohol, and ether, but hydrochloric acid, and various alkaline salts, dissolve it completely, producing soluble double salts with it. Its composition is—

		Centesimally.	
1 Eq. of Mercury,	100	44.25	
1 Eq. of Iodine,	126	55.75	
1 Eq. of Iodide of mercury,	226	100.00	

agreeing with the formula $Hg I$.

Iodide of mercury might be used as a pigment. It has been stated by several French chemists, that its employment was contemplated some few years ago by English dyers and printers, for giving a bright color to cloths, but the Editor has not been able to learn anything of its application in this way.

Iodide of Silver.—This salt is easily prepared by adding to a solution of a soluble silver salt, an aqueous one of hydriodic acid, or of a soluble iodide. It forms a yellowish-white precipitate, which, when dried and heated, fuses to a reddish liquid mass, but changes to a dirty yellow.

The same salt is formed when iodine is made to act upon silver foil; or, according to M. ST. CLAIRE DE-

VILLE, when concentrated hydriodic acid is poured upon the metal, hydrogen being abundantly eliminated. It is found native, as specified in the beginning of this article. Iodide of silver is soluble in an excess of the alkaline iodide to some extent, but is only sparingly dissolved by water; it is not dissolved wholly by ammonia, like the chloride of this metal. In the presence of moisture, chlorine decomposes the iodide of silver, yielding a chloride of the metal and free iodine, which may be expelled by slightly raising the temperature. This reaction does not take place at a high temperature, as ascertained by M. ST. CLAIRE DEVILLE, but, in fact, hydriodic acid is capable of expelling hydrochloric acid from chloride of silver, and producing an iodide instead, contrary to the received opinion of the force of the affinity of these elements. He also found that on making a mixture of hydrochloric and hydriodic acids, and adding it to a solution of a soluble silver salt, only iodide of silver was produced. Chlorides of potassium and of sodium, dissolved in a small quantity of water, dissolve iodide of silver freely. Strong nitric and sulphuric acids are capable of liberating iodine from the iodide of silver, a nitrate or sulphate of the oxide of the metal being formed; this does not happen, however, when water is present, or the diluted acids are employed. Iodide of silver contains—

		Centesimally
1 Eq. of Silver,	108	46.15
1 Eq. of Iodine,	126	53.85
1 Eq. of Iodide of silver,	234	100.00

consequently, its formula is Ag I.

The chief use which is made of this body is in Photography, and the various other systems in use for taking impressions of objects by the influence of light. As, however, in a future article this beautiful and very interesting art will be fully discussed, the action of light upon the salt in question will not be further pursued here.

Estimation of Iodine when uncombined and in combination.—The minute proportion of this element, which has often to be sought in plants, bituminous and other shales, waters, and even in the air, has taxed the inventive powers and researches of chemists for methods, of which the accuracy might be commensurate with the evident difficulty of the task undertaken. Fortunately, iodine comports itself with a few bodies in such a characteristic way, offering indications so marked as not to be surpassed in this respect by any other substance known. These are starch, silver, and palladium; and by proper modifications in the applications of only these three bodies, the methods for the estimation of iodine, as well when free as when combined, are not exceeded by any other class, either in their accuracy or extent.

Some of these methods are of recent invention, whilst others date from the first researches made upon this element by GAY-LUSSAC and others. Iodine in quantitative determinations is never weighed alone, but in combination with another body, with which it is chemically united—silver or palladium. These offer the greatest security for accurate results, since they produce compounds with the iodine which are unaffected by most

other substances. As a preliminary to the estimation either by silver or palladium, it is necessary to convert the iodine into hydriodic acid or into an alkaline iodide; and for this purpose a sample is weighed, and treated by any of the convenient methods already detailed for the production of hydriodic acid or iodides of the alkalies. If the iodine is mixed with potassa sparingly, and the brownish liquid treated with sulphide of hydrogen till it becomes colorless, iodide of potassium results; but in adopting this process, the last traces of the sulphide of hydrogen must be expelled, so as they may not interfere with the subsequent precipitation with nitrate of silver. A solution of the latter salt with a little nitric acid is then added as long as any precipitate is formed. By placing the beaker in a warm situation, the yellow iodide of silver falls, and the supernatant clear liquid may be decanted; the residue in the beaker may be washed either by adding water to it, agitating, and after it has subsided pouring off the clear solution, or it may be thrown upon a filter, washed thoroughly, and dried in the water-bath. The bulk of the precipitate is detached from the filter, and introduced into a porcelain crucible; the paper being burned on the lid at as low a temperature as possible, and the ashes added to the matter in the vessel. Subsequently, the whole is heated to a low red heat, and when cold, weighed. From the weight of the substance, minus that of the filter-ash, that of the iodine is calculated—234 parts of iodide of silver being equivalent to 126 parts of iodine.

In conducting this operation, it would be better to wash the precipitate by decantation, and afterwards to transfer it into the crucible, evaporating the water from the latter in the bath, and finally slightly heating over the lamp and weighing. No loss would be incurred in this by reduction of any part of the compound, as is done when a filter is employed. In either case, however, the results are very accurate. When a palladium salt is at hand, the mode introduced by LASSAIGNE is still better, and is now almost in every instance preferred to that just described. It is the more certain and convenient, as it offers a means of determining the iodine, even in the presence of chlorine and bromine, which the use of silver does not. The following is the method:—The liquid containing a weighed portion of the iodide under examination, or of the iodine converted into an iodide or hydriodic acid, is to be slightly acidulated with hydrochloric acid, and a solution of the protochloride of palladium added as long as a precipitate continues to form; the vessel is then placed in a warm situation for twenty-four or forty-eight hours, at the end of which time the clear liquid is passed through a filter, and the russet-black precipitate collected; it is washed with warm water, and subsequently dried till the weight remains constant, and the iodine calculated from the quantity of iodide of palladium thus found. As it is somewhat difficult and tedious to dry the precipitate when washed with water, it would be well to pour some alcohol upon the filter, after all the impurities have been first removed by the hot water, and after the spirit has passed through, to replace it with a little ether. When exposed to heat, the volatile liquid will readily escape, leaving the mass quite dry. FRESSENIUS

recommends to exsiccate the compound in *vacuo* over sulphuric acid. As the iodide of palladium is decomposed into iodine and metal by heat, the weight of the compound is taken after driving off all moisture by long exposure to a low temperature, or as above described; and as this is done in contact with the filter, the latter ought to be tared before collecting the salt, and after being exposed some hours to a heat of a water-bath. One hundred and seventy-nine parts of the dried salt—palladium 53 + iodine 126—contains one hundred and twenty-six of iodine. According to ROSÉ, the iodide after desiccation may be heated in the usual way in a platinum or porcelain crucible, and from the weight of the palladium which is left, the iodine calculated. LASAIGNE found that the $\frac{1}{400,000}$ th part of iodide of potassium could be determined in a liquid by this means, and the modifications, to which reference will be made presently, show that this is fully corroborated.

Upon the reaction of chloride of palladium with hydriodic acid or a soluble iodide, KERSTING has founded a volumetrical method of analysis for determining this element. He prepares for the purpose a number of test liquors with pure iodide of potassium and protochloride of palladium; the iodide of potassium solution is made of such a strength as to contain one part of iodine in a thousand of the liquid. This is done by dissolving 13.1 parts of the ignited salt in ten thousand parts of distilled water.

The palladium test liquor is prepared by dissolving one part of the metal in nitrohydrochloric acid with the aid of heat, evaporating the solution to dryness in a water-bath, and adding to the residue fifty parts of concentrated hydrochloric acid and two thousand parts of water, agitating the whole, and then allowing it to rest, to part with any insoluble matter. The value of this liquid is to be ascertained by adding to a given volume of it the iodide of potassium solution in successive portions, till the whole of the metal is thrown down. If the iodide test liquor be poured from a burette holding one thousand grains of water, and divided into one hundred divisions, the amount of palladium in the volume of solution operated upon may be readily ascertained from the number of measures of the other added, since each division contains exactly 0.1 grain of iodine, which is equivalent to 0.042 of palladium, since $126 : 0.1 :: 53 : 0.042$.

Having thus ascertained the quantity of materials in the two test liquors, the iodide to be examined is dissolved in water, if it admits of this treatment; a certain measure is then taken and operated upon qualitatively, as it were, in order to arrive at a knowledge of the probable quantity of iodine contained in it. For this purpose a number of measures of the palladium liquid is taken in a flask and heated in the water-bath; the measures of the liquid under examination are diluted till the ten make one hundred or a thousand grains. After the palladium solution is warmed, the other is dropped in from the burette in portions, taking care not to add too much at once, and also to shake the flask after each addition. The precipitate readily falls, and by drawing off, by means of a pipette, two portions of the liquid into two tall narrow foot-glasses, and adding to one a few drops from the burette and comparing

it with the other, it will be readily ascertained whether the whole of the palladium has been thrown down. If not, a further addition is to be made to the solution in the flask, to which the portions taken out for trial-tests must be put, and the whole left for a short time in the bath, heated as before from 140° to 212°, and as soon as the solid has settled to the bottom, a similar trial-test made. It is needless to say, that as the precise point is approached, the solution of iodide of potassium must be added more sparingly, and, when gained, the two liquids ought to be tested with the iodide of potassium and with the palladium liquor, using the former in one of the test-glasses, and the latter in the other. If no indication is obtained, it is proof that the whole of the palladium has been precipitated. Should, however, an excess of the iodide be added, the operator ought to introduce a few measures of the palladium test, and proceed more carefully in the precipitation till the desired point is attained. From the number of measures of the metallic solution operated upon, it is easy to ascertain the iodine, calculating from the data given in the preceding. A second test may now be performed, employing a given number of measures of the solution containing the iodine, and adding the other test solution till there is no further separation of iodide of palladium, in order to arrive at the true amount of iodine with greater certainty.

If the iodide under examination should be insoluble in water, or not well adapted for immediate solution, on account of admixture with foreign substances, it must be distilled from a small retort, with the neck turned upwards, with sulphuric acid, using for this purpose about twenty measures of the burette of strong acid, free from iodine, and from twenty to a hundred measures of water. The distillation must be continued till fumes of hydrated sulphuric acid begin to be evolved. Should the distillate contain free iodine and hydriodic acid, a few drops of starch paste, prepared by boiling one part of starch with one-tenth part of strong sulphuric acid in twenty-four of water, and then sulphurous acid, till the blue coloration occasioned by the free iodine and starch disappears, or is on the point of disappearing; on the other hand, if the substance distilled with the acid contains organic matter, causing, during the operation, an evolution of sulphurous acid, which condenses in the receiver, a few drops of the paste must be introduced, and then a solution of bleaching powder, till a faint bluish tinge begins to appear. This is an indication that the whole of the sulphurous acid has been converted into sulphuric acid; it is necessary, however, to destroy the azure tinge in the liquor by a few drops of solution of the sulphurous acid. After this, the testing with the palladium liquor is proceeded with in the manner detailed.

According to KERSTING, dilute hydrochloric, sulphuric, nitric, phosphoric, and acetic acids, and also the neutral salts of those acids with the alkalies, have no influence upon this method; neither have chloride of calcium or of zinc, acetate of lead, sugar, uric acid, and the distillate of urine with sulphuric acid, alcohol, ether, starch paste, oil of lemons, and bromide of sodium, in the presence of acetic acid. The test is interfered with, however, by the presence of alkaline

bromides with free mineral acids, especially upon heating; free alkalis, free chlorine, bromine, iodine, and cyanogen; large quantities of nitric acid at a high temperature, and sulphurous acid; for all these bodies prevent the precipitation of the iodide of palladium.

KERSTING has devised another mode, which is in application less complex than the foregoing, and affords, when none of those substances which interfere with the reaction are present, very trustworthy results. It is founded upon the behavior of chloride of mercury with a metallic iodide, tinged blue by the addition of a little starch paste and bromine water, in which case coloration is perceived as long as any of the iodide remains undecomposed by the mercurial salt, but by the decomposition of the last traces the blueness disappears. A test liquor, containing a certain known weight of chloride of mercury in a given volume of it, is prepared as in the preceding case, and the iodide to be examined is dissolved, and the liquor so diluted that it will contain about one part of iodine in a thousand, being previously blued by a little bromine water and starch paste, as previously mentioned. By adding the test liquor to this solution, iodide of mercury and chloride of the metal, in combination with the iodide, will be formed; but in consequence of the solutions being so diluted, the mercurial iodide dissolves, and so does not prevent the observation of the blue shade. When this disappears, the number of measures of test liquor required are read off, and from them the iodine is calculated. 135.5 parts of chloride of mercury are equivalent to 126 of iodine, and so in this proportion will any weight of the former salt in the solution added to destroy the color, be to its equivalent of iodine. When chlorides and bromides are present, also free mineral acids, acetic acid, and the acetates, the results afforded by this method are not exact.

Dr. FREDERICK PENNY has published a process for testing the quantity of iodine in iodides, volumetrically, by means of bichromate of potassa, which gives rise to the annexed reaction:—

When heat is not applied, this is the only reaction which takes place, and by it three equivalents of iodine are set free by one of the bichromate of potassa. The manipulations are as follow:—Ten grains of pure bichromate of potassa are dissolved in about seventy measures of the burette, holding one thousand grains of water up to zero on the divided scale, and the remainder up to 0, filled with strong cold hydrochloric acid. The liquor is agitated and set aside. A weighed quantity of the salt to be examined is taken and dissolved in like manner in about a thousand grains of water, and to this the liquor from the burette is added cautiously till the whole of the iodine is precipitated. This is ascertained by letting a drop from the end of the glass-stirrer fall upon another of a freshly-prepared solution of protochloride of iron, mixed with sulpho-

cyanide of potassium, and observing if a red coloration be produced. The bichromate solution is carefully added, stirring after each addition till this result is arrived at, and then the number of measures read off. Knowing that every ten divisions of the test solution contains one grain of the bichromate, and that their quantity effects the liberation of 2.437 grains of iodine from the sample, it is easy to estimate the weight of iodine in the quantity operated upon by the proportion:

$$10 : 2.437 :: x : y \text{—the iodine.}$$

Before leaving this part of the subject, which must be interesting to every chemical student, it may be well to lay BUNSEN'S volumetrical method before the reader. It is founded on the behavior of sulphurous acid with iodine, which, in the presence of water, converts the iodine into hydriodic acid:—

This reaction is one among the many that the chemist and manufacturer encounter, and which at first sight appears inconsistent, since the converse can be effected as freely, namely:—

The state in which the substances are presented to one another has a great influence upon the nature of the change, and, consequently, demands careful study. In this case, the one or other of these reactions which result, is dependent upon the state of concentration of the materials which are taken to produce the effect. By careful experiments, BUNSEN found that the first reaction only is produced when a solution of sulphurous acid, containing 0.04 to 0.05 of real acid, is brought into contact with iodine; hence, when this condition is supplied, one equivalent of sulphurous acid is converted into sulphuric acid by an equivalent of iodine.

This comportment suggests, that when an unknown quantity of iodine is mixed with an excess of sulphurous acid of the above strength, by testing how much of the reagent remains in excess after the former substance has disappeared, the difference will afford data for calculating the quantity of iodine present. By means of a solution containing a known amount of iodine, the latter part of the reaction is performed.

Standard solutions of sulphurous acid, of the fore-mentioned strength, also one of iodine, one of iodide of potassium, and some starch paste, are required for performing the analysis by this method. The iodine test liquor is prepared by dissolving five grammes of the purest iodine in a concentrated solution of pure iodide of potassium, in a flask holding twenty thousand grains measure—twenty measures of burette—up to a certain mark, and diluting the liquor with distilled water till this mark is reached. A perfect homogeneity of the liquid should be effected by agitation, and care taken that it does not show any brown tinge. As each hundred divisions of the burette of this liquid contains 0.25—2000 : 5 :: 100 : 0.25—it is evident that

each division will contain a quantity of iodine equal to $\cdot 0025$ of a gramme. Lest impurities might be contained in it, it is necessary to subject it to a corroborative test to be certain of its value.

A sulphurous acid test liquor is prepared by saturating distilled water with sulphurous acid at the common temperature; this liquid should be kept in well-stoppered bottles inverted in water. From seventy to eighty divisions of this saturated liquor should be added to every hundred burette measures of distilled water.

The iodide of potassium test liquor is prepared by dissolving one part of pure iodide of potassium in ten parts water; it should form a colorless liquid, and give no tinge even on the addition of hydrochloric acid.

It is necessary to prepare the starch paste fresh for each testing. Before proceeding to operate upon samples of unknown composition, it is requisite to find the relative proportion between the iodine and sulphurous acid solutions; and also what quantity of the respective agents is present in a given volume of them. To effect this, it is required, in the first instance, to measure off two burette measures, that is, two hundred burette divisions of the diluted sulphurous acid solution, and add thereto six or eight divisions of starch paste; then a solution of the iodine is dropped in from the burette, and the flask agitated till there is a slight excess of the iodine, and the starch acquires in consequence a persistent blue color.

Operating in this way, and supposing that, to convert the two hundred divisions of sulphurous acid into sulphuric, one hundred and eight of the iodine liquor were required, it is evident that these numbers will stand in the same relation to one another when the iodine is to be determined, as when it is wished to estimate the sulphurous acid. The next step is to find how much pure iodine is contained in each degree or burette division of the iodine test solution, and likewise its effect upon the sulphurous acid. This is done by weighing off $0\cdot 40$ gramme of dry and pure bichromate of potassa, and treating it in a small retort with concentrated hydrochloric acid, and conducting the evolved chlorine into a solution of iodide of potassium. For this end the bichromate and acid are put into a flask, to which a tubulure and tube are adapted, and secured by passing a tube of caoutchouc over the neck, cork, and portion of the tube; a small glass bulb, with its long neck closed by the blowpipe, is put into the end of the eduction tube, and then introduced into an inverted retort, containing the solution of iodide of potassium. Heat is applied by means of a lamp, and, after a few minutes' ebullition of the contents of the flask, the whole of the chlorine will have passed over. There will be liberated from the iodide of potassium, by the chlorine evolved from the quantity of bichromate operated upon, $1\cdot 024$ of iodine—that is, an amount proportionate to three equivalents of iodine for one of the former salt, as stated at page 400. To the solution containing the mixture of iodine and iodide of potassium, the diluted sulphurous acid liquid must be added from the burette till the brown color of the fluid has completely disappeared, and the quantity is noted, which, for example's sake, may be taken at sixteen hundred divisions. It is needless to say that there has

been an excess of the acid employed on this occasion, and which is to be determined in the next operation, by introducing a little starch paste, and as much of the standard iodine solution as is requisite to communicate a blue color to the fluid. If for this purpose twenty divisions of the burette are taken, from the following calculation, founded upon the preceding tests, the value of the solution as to the iodine it contains, and the sulphurous acid it changes into sulphuric, is arrived at. As by the previous experiment it was found that fifty-four divisions of the iodised solution were necessary to oxidise two hundred of the sulphurous acid liquor, it follows that four hundred and thirty-two of the former will be required to oxidise the one thousand six hundred measures taken of the latter; but, as the experiment shows that the iodine liberated from the iodide of potassium is equivalent to this volume of test liquor, minus the twenty divisions required for the excess—that is, $432 - 20 = 412$ divisions, corresponding to $1\cdot 024$ of iodine—it is evident that each burette division of the iodised test liquor contains $\cdot 00248$ of a gramme of iodine. Of course, each degree of the entire quantity of the test liquor possesses this value.

To test the iodine in a sample submitted, a portion is to be weighed off in a flask, and dissolved in iodide of potassium of the strength specified in the foregoing, using about ten divisions of the burette for each one-tenth of a gramme of the iodine. The dilute sulphurous acid liquor must now be added in measured quantities from the burette, till all color in the solution disappears; the quantity thus used is noted; a few divisions of starch paste are stirred with the menstruum, and the iodine test liquor carefully dropped in, stirring well after each addition till the blue iodide of starch appears. The volume of sulphurous acid and the number of divisions of the iodised test liquor which are required to oxidise the excess of the acid above what was necessary to convert the iodine in the sample to hydriodic acid being known, it is easy to find, by the following mode of calculation, the proportion of iodine in the sample. Thus, supposing that a thousand divisions of the acid solution were taken in the first instance, and that to oxidise the excess which remained of this, ten divisions of the iodine liquor were required, it follows that the weight of the sample taken, supposing it a gramme, contained $0\cdot 6448$ of iodine, and, consequently, $64\cdot 48$ per cent.; for, as found by the foregoing experiments, fifty-four divisions of the iodine liquor were equivalent to the oxidation of two hundred of the sulphurous one; hence $200 : 54 :: 1000 : 270$, and $270 - 10 = 260 \times \cdot 00248$ —the amount of iodine in each division—gives $0\cdot 6448$, as stated.

For the detection of the grosser adulterations of iodine, which are mentioned as being practised, although they have not come within the range of the Editor's experience—such as plumbago, sulphide of antimony, and the like—a rough estimate may be formed of the amount, by heating a weighed sample of iodine in a porcelain crucible to redness, till the whole of this element is volatilized, and weighing the fixed residue. This, though not so precise as those other methods which have been detailed, does not require that accu-

racy of manipulation which is presupposed to be possessed in the other instances.

When small quantities of iodine have to be found—as, for instance, in the ashes of plants, the residuary matter left after the evaporation of spring or river waters, and the like—the methods by which they are to be detected must evidently insure all possible accuracy, if the investigator is anxious to arrive at the truth. For a long time the tests known, such as decomposition of the iodide by sulphuric acid, and addition of starch paste, were found insufficient to determine the minute traces of iodine which, as appears by late researches, are contained in several bodies. Without entering upon the general description of all the tests proposed, a few of the more remarkable may be briefly noticed.

At the head of investigations of this kind stands the test of PRICE, detailed in the Transactions of the Chemical Society for 1851. It consists in operating upon the solution which is supposed to contain the iodide with hydrochloric acid and starch paste, and then adding a few drops of a solution of nitrite of potassa, when a blue coloration from the iodide of starch makes its appearance. The hydrochloric acid liberates the iodine from its basic combination, and is retained in the liquid in the form of hydriodic acid; this body is decomposed by the nitrite, the acid of which is set free by the excess of hydrochloric acid—the hydrogen being converted to water, and the iodine liberated. When much iodide is present, the color of the liquid is dark blue, and appears immediately; but when only a small quantity is contained in the substance operated upon, the shade is lighter, and a few seconds elapse before its appearance. This chemist states that he has detected iodine in a solution containing not more than the four-millionth part of it, and that there is no difficulty in ascertaining the presence of iodine in cod-liver oil, and in the mother-liquor from a few pounds of sea-water, by its aid.

M. GRANGE's method is analogous to that just described, only that he directs the transmission of a few bubbles of fuming hyponitric acid through the solution to be tested, and already impregnated with starch paste; the reaction is instantaneous; and when the iodine forms about the five-millionth part of the fluid, a pale rose color, inclining to violet, is produced. With a larger proportion, say the one three hundred thousandth, this chemist asserts that the characteristic blue appeared; but when only the one-millionth of iodine is present, he states that no satisfactory results can be attained by this test *per se*. Coupling it, however, with another method published by RABOURDIN, founded upon the property of chloroform, of dissolving iodine, and becoming reddish-coloured thereby, it can be rendered so accurate as to satisfy the minutest inquiry. Should a portion of the fluid afford no indication with starch paste and hyponitric acid, the latter is to be transmitted through the bulk of the solution at hand, till it manifests an acid reaction; a small quantity of chloroform is agitated with it, and then drawn off with a pipette; the reddish color is removed by the addition of a little potassa, and the aqueous solution then decanted. The hyponitric test is then applied, when it does not fail to produce the characteristic blue color.

In this way, the one-five millionth of iodine is easily detected. GRANGE found that bromides do not interfere with the accuracy of these reactions, for they are not decomposed by the hyponitric acid.

M. MORIDE has proposed a substitute for the chloroform in the preceding method, which offers advantages in giving a solution which is more highly colored than the chloroform becomes under similar circumstances. According to this chemist, wherever iodine is indicated by starch paste, it may be proved also by the employment of benzine more satisfactorily. This agent is rendered more valuable from the fact, that the water which is present, or which may be used to wash it, carries away any bromine or chlorine, thus leaving the iodine isolated.

Chlorine, though capable of setting iodine free from its combinations in aqueous solutions, is now rarely employed to detect iodine, since an excess of the agent converts the iodine into a colorless combination of chloride of this element. Bromine comports itself differently, for although it is capable of liberating it, still none of the iodine is redissolved. DE LUCCA has made this behavior the basis of a method for the analysis of iodides by means of a standard solution of bromide, coupled with the use of sulphide of carbon, which takes up the iodine as it is liberated by the bromine liquor. From the volume of the latter which is expended in setting free the whole of the iodine—ascertained by the sulphide of carbon being colorless when drawn off with the pipette—its quantity is found.

To show that iodine is contained in the air, *et cetera*, modifications of the processes above described have been successfully employed by CHATIN, HERAPATH, and others; but to enter into further details upon this subject, although highly interesting, appears unnecessary.

IRON.—*Fer*, French; *Eisen*, German; *Ferrum*, Latin.—Iron is a metal of a bluish-grey color, but acquiring a brilliant surface by polishing; its fracture is fibrous, and it is the hardest and toughest of all the ductile metals; it cannot be hammered into very thin plates, but may be rolled into thin sheets, and drawn into very fine wire.

The iron of commerce is seldom or never pure, containing small portions of carbon, sulphur, silicium, phosphorus, arsenic, *et cetera*; its density varies a little according to its purity and the mode of its manufacture. Purified by fusion with smithy scales, it gave in some experiments a specific gravity of 7.8439, which is increased by rolling and drawing into wire. Pure soft bar-iron, containing only a trace of carbon, has a density of 7.79; that of ordinary bar-iron is 7.788.

When iron is subjected to a red heat, it softens and becomes tough, a circumstance which adds much to its value in the manufacturing arts; and its property of welding at a white heat, gives a facility in working it which no other metal possesses. When heated above the welding point, it crumbles under the strokes of the hammer.

The melting point of iron has been variously given as 1550° C.—*Pouillet*; 1587°—*Daniell*; 6346° C. or 175° Wedgwood—*Morveau*; 158° Wedgwood—*Mackenzie*. Any impurity in the metal makes it more easily fused,

and might account for small discrepancies in the melting point; but the remarkable differences shown in the above results enable us to appreciate the great difficulty of obtaining accurate measurements of very high temperatures.

Iron is attracted by the magnet, and is itself easily rendered magnetic, but does not retain this property except when converted into steel.

HISTORICAL NOTICE.—Iron, wherever known, has universally taken the lead amongst the metals in point of usefulness, and its possession by any people has invariably proved the means of advancing them in the arts of civilized life, and of raising them in the scale of nations. It is strange that, notwithstanding the difficulties in its manufacture, iron is amongst the first metals mentioned in history. MOSES tells us that TUBALCAIN, the great-grandson of CAIN, ADAM's son, was an instructor of every artificer in brass and iron, that iron furnaces were in use in ancient Egypt, and that the hills of Palestine produced ferruginous ores. JOB says,—Iron is taken out of the earth;—and throughout the whole sacred volume this metal is referred to as being in common use, both for weapons of war and manufacturing instruments.

HOMER mentions a mass of iron as one of the prizes at the funeral games given by ACHILLES in honor of PATROCLUS, a circumstance showing the great value attached to it in ancient times, when it was so much less common than at the present day:—

Then hurl'd the hero, thundering on the ground,
A mass of iron—an enormous round—
Whose weight and size the circling Greeks admire,
Rude from the furnace, and but shaped by fire.

* * * * *
Who furthest hurls it takes it as his prize.
If he be one enriched with large domain
Of downs for flocks, and arable for grain,
Small stock of iron needs that man provide;
His hinds and swains whole years shall be supplied
From hence; nor ask the neighboring city's aid
For ploughshares, wheels, and all the rural trade.

There are also notices in HOMER and HESIOD of the methods of reducing and forging iron; but cast-iron was then unknown, an imperfectly malleable iron being produced at once from the ores in the furnace. It is conjectured that the Greeks obtained most of their iron through the Phœnicians, from the shores of the Black Sea and of Laconia. DIODORUS SICULUS refers to the Island of Elba as yielding ores of iron, which the natives were accustomed to dig and cut out of the ground, subsequently melting the mass to obtain the metal. PLINY in his Natural History enters at great length upon the manufacture of iron; he says the ores are to be found almost in every country, and that they are easily discovered by the color of the earth which breedeth the iron, and that they are tried by fire like other veins of metal. He speaks of it also as being applied to all the uses for which it is commonly employed in the present day. It is remarkable, however, that although in all the Latin writers, *ferrum*, iron, is the most common name for a sword, the weapons and cutting instruments discovered in the ruins of Pompeii and Herculaneum are almost invariably found to be made of bronze.

The furnaces which were first employed for smelting

iron were probably simple conical structures, with small openings below for the admission of air, and a large one above for the escape of the products of combustion, erected on high grounds that the wind might assist combustion. Similar rude furnaces, known as *air-bloomeries*, are still used in some countries at the present day. Successive layers of ore and charcoal being placed over the fire, the heat would be regulated by opening and closing the apertures. Subsequently, an artificial blast would be introduced, and the advantages of this appear to have been known at a very early period; for HOMER represents HEPHÆSTUS as throwing the materials from which the shield of ACHILLES was to be forged, into a furnace urged by twenty pair of bellows. This blast-bloomery would ultimately be developed into the *catalan forge*, in which malleable iron is produced directly from the ore by heating it in contact with carbon—a process still adopted in some places where wood is abundant for making charcoal, as in the Pyrenees, in Corsica, and some parts of Spain. Finally, it assumed the form of the *blast-furnace*, now in general use, and which, by completely fusing the ore in contact with the fuel, results in producing cast-iron—a compound of the pure metal with carbon.

The transformation of the blast-bloomery into the blast-furnace is supposed to have taken place in the early part of the sixteenth century; for proof exists that in the seventeenth the art of casting had arrived at considerable perfection. The more efficient operation of the blast-furnace allowed the reduction of the heaps of scoriæ, which had been gradually accumulating during the period that the blast-bloomeries had been in operation. In the Forest of Dean in Monmouthshire, in Yorkshire, and other counties, these were found in immense beds, among which were discovered Roman coins and other specimens, inscribed to the god who presided over iron. There is ample evidence of the industry of the Romans in working the iron mines of Britain, until their final abandonment of the island about A.D. 409. It is supposed, also, that the Danes, during their occupation of England, carried on the smelting of iron extensively, and hence many of the heaps above-mentioned are called in certain localities *Danes' cinders*. A portion, only, of the ore was reduced by the imperfect methods of smelting then known; and, in the Dean Forest alone, it is computed that twenty furnaces, for a period of nearly two hundred years, were supplied chiefly with the bloomery cinders as a substitute for iron ore.

Up to the beginning of the seventeenth century, charcoal was the only material employed in smelting operations. An enterprising ironmaster in Worcestershire, named DUDLEY, was the first who attempted the operation with pit-coal, and the trial was so successful, that about the year 1620 he applied for a patent for his invention, which was granted for thirty-one years. For some time he succeeded in producing considerable supplies of iron, which could be sold with good profit at a much reduced price; but this very success was the cause of his ruin, by exciting the animosity of his rivals, from whom he encountered incessant opposition, and, by combinations among masters and men, he was ultimately turned out of his works. With DUDLEY

died for a time the art of making iron with pit-coal; but the rapid destruction of the forests, not only to supply the great consumption of the blast furnaces, but also the wants of a constantly increasing population, induced at length special enactments prohibiting the cutting down of timber for the use of the ironworks. The first effect of this prohibition was greatly to reduce the number of furnaces; so much so, that in 1740 the annual production, which had previously amounted to one hundred and eighty thousand tons, was diminished to seventeen thousand three hundred and fifty tons.

The change from charcoal to coke as fuel necessitated a more powerful blast, and a longer subjection of the materials to the heat. The latter was effected by an enlargement of the height of the furnace, and the former by the introduction of large cylinders, with closely fitting pistons, instead of the common forge-bellows. The earliest blowing cylinders of any magnitude are supposed to have been those erected by SMEATON at the Carron Ironworks in 1760. These improvements speedily effected an astonishing increase in the production of iron. About the year 1780, the furnaces still worked with charcoal produced only eleven tons of iron weekly, while those in which coke and coal were used averaged a weekly product of seventeen and a half tons. DR. URE gives the quantity of cast-iron produced in 1788 as follows:—

	Tons.
By means of coal,.....	48,800
By means of charcoal,.....	13,100
Constituting a total quantity,.....	61,900

In 1796 the wood-charcoal process was all but entirely given up, and the gross produce of one hundred and twenty-one blast furnaces was one hundred and twenty-four thousand eight hundred and seventy-nine tons, being near to twenty tons weekly for each furnace; and in ten years after this, 1806, there were two hundred and twenty-seven blast furnaces in this country, one hundred and fifty-nine of which were in active blast at once, and produced two hundred and fifty thousand tons of iron.

The blast furnaces were distributed as follows:—

In the principality of Wales,.....	52
In Staffordshire,.....	42
In Shropshire,.....	42
In Derbyshire,.....	17
In Yorkshire,.....	28
In the counties of Gloucester, Monmouth, Leicester, Lancaster, Cumberland, and Northumberland,.....	18
Scotland,.....	28

227

Nearly simultaneous with the earliest improvements in the manufacture of cast-iron by means of pit-coal, were others of an equally important kind for converting the cast-iron into malleable or bar-iron. Hitherto this had been effected by means of wood charcoal in what are termed refiners, as is still practised in the South of France; but owing to the scarcity of wood fuel in this country, the charcoal was mixed up with coke for the refining operation; the iron produced from this was hard and of an inferior quality, and much time was required for the conversion of a ton of cast into malle-

able iron. England was therefore greatly indebted to Sweden and Russia for iron of good quality, and not less than seventy thousand tons annually were imported from these countries. In 1783, MR. RICHARD CORT, after many trials, succeeded in converting cast-iron into malleable iron, by the use of pit-coal in a reverberatory, instead of a blast furnace, and thus introduced what is known as the *puddling process*. For some time much difficulty was experienced in puddling, from the loss of iron, and irregularity in the quality of the metal produced and the fuel used. To avoid this, the iron was subjected for a short period to a process of refining with the blast and coke fuel, previous to being transferred to the puddling operations in the reverberatory furnace. The original puddling furnace, patented by MR. CORT in 1784, says MUSHET, is now, *without the intervention of the refining*, producing tens of thousands of railway bars all over the world. This invention placed England in an independent position as respects iron, and so facilitated the manufacture of malleable metal, that before many years one work could turn out annually as much bar-iron as was made previously by the whole iron trade of the kingdom. Notwithstanding the value of these improvements, MR. CORT did not benefit by his inventions. After spending thousands in experimenting, and giving to the world his results, those who were the gainers repudiated his claims while they adopted his processes, leaving him to drag out the rest of his days in poverty; and it was only in the course of last year that the Government granted a small acknowledgment of fifty pounds per year to the widow of the great benefactor of his country, while the children and grandchildren have been appealing to the sympathy and charity of the ironmasters, for what they should have received through their father as a right.

The general introduction of the steam-engine, as improved by WATT, contributed also to initiate a new era in the history of the iron trade, as in almost every branch of industry. Its application to pumping enabled the mines to be sunk to a greater depth, and accelerated the process of raising the coal and ores; by employing it as the motive power for urging the blast, refractory ores were reduced with facility, and the processes of rolling, forging, *et cetera*, were now effected with a rapidity previously unknown.

Lastly, the discovery of the hot-blast process, for which a patent was taken by MR. NELSON of Glasgow in 1824, and by which three or four times the quantity of iron can be produced with little more than one-third of the fuel that was required with the cold-blast, effected another complete revolution in the iron trade, and may be regarded as marking the last era in the history of this all-important metal. The high expectations at first formed from BESSEMER's new and remarkable refining process, of which an account will be given, have not yet been realized.

SOURCES.—In admirable harmony with the universal application and innumerable uses of iron, is its almost universal presence in nature. It is by far the most widely diffused of all the metals; there being few substances in the material world that do not contain it in greater or less amount; and yet the variety

of ores from which the metal is manufactured is very limited.

Native Iron.—For a long time native iron was unknown, and its existence in nature questioned; it has been found, however, in several localities both on the Continent of Europe and in America. In this country it has been met with in minute quantity in trap rocks, but on all occasions it is found only in small portions, and is considered more in the light of a chemical or mineralogical curiosity than as a useful source of the metal. Native iron is almost pure white, more resembling silver than ordinary iron, is generally softer and less dense, and, unlike meteoric iron, contains no nickel. A mass was found with magnetite at Grass Ramsdorf, not far from Saalfeld in Thuringia, which, according to KLAPROTH, consisted of:—

	Centesimally.
Iron,	92·5
Lead,	6·0
Copper,	1·5
	100·0

It is said, however, to be found in considerable quantity in Liberia. The natives use it for instruments; it is soft and flexible, and can be easily cut with a chisel. An analysis of this gave:—

Iron,	98·87	98·40
Silica,	1·63	1·60
	100·00	100·00

This is the purest yet described from any locality. In 1786, a mass of native iron, weighing upwards of thirteen tons, was found in South America, a sample of which was sent to the British Museum. It is described as being soft and compact, although the internal part of the mass is full of cavities; it had every appearance of having been in a fused state, and was considered the product of a volcanic irruption. No analysis of this sample has been made.

Small quantities of native iron have been obtained in the immediate vicinity of a coal seam which had been spontaneously ignited, and was doubtless the result of reduction by the coal; samples of this sort are excessively hard and fine-grained, and give a fracture resembling cast-steel, from which circumstance it has been named *native steel* or *steely iron*. A mass of this mineral, weighing sixteen pounds six ounces, was discovered some years since near Nexy, in the department of the Allier.

Meteoric Iron.—Large masses of metallic iron have been discovered from time to time, in different parts of the globe, embedded in the soil and also lying upon the surface; others of a similar kind have been known to fall from the atmosphere, and are hence termed meteorites. These masses are generally covered over with a kind of black enamel, which protects the metal from the action of the atmosphere. The iron forms usually a sort of network round a crystallized metallic mineral of a complicated composition. These meteoric masses are sometimes so large, and the metal which they contain so pure, as to furnish the inhabitants of the neighborhood with ample material for knives and spearheads. When examined chemically, there seems

a considerable similarity in the composition of different specimens, although some of them contain ingredients which others do not. In the following table this similarity is very apparent, although the samples were obtained from localities widely apart:—

No.	Iron.	Nickel.	Cobalt.	Copper and tin.	Manganese.	Phosphorus.
1	92·47	5·67	0·23	—	—	—
2	93·77	3·81	0·21	—	—	—
3	88·04	10·73	0·45	0·66	0·13	—
4	88·23	8·52	0·76	—	—	—
5	66·56	24·70	—	—	—	—
6	83·57	12·66	—	—	—	—
7	89·78	8·88	6·67	—	—	—
8	85·61	12·27	0·89	—	—	—
9	90·88	8·45	0·66	—	—	—
10	88·98	10·35	—	0·56	—	0·11
11	85·00	13·01	1·42	0·57	—	—
12	86·64	13·04	—	0·27	—	0·05

These are but a few of many analyses that have been given, all showing a remarkable sameness in composition. Besides these ingredients, the meteoric mass is sometimes found to contain silica, alumina, lime, potassa, chromium, magnesia, soda, arsenic, carbon, sulphur, chlorine, *et cetera*.

Protoxide of Iron.—This oxide has never been found in nature except in combination with other matters, forming distinct minerals. Its great tendency to combine with more oxygen, obtained either from the air or other substances, prevents it existing as protoxide for any length of time, unless it is entirely excluded from the presence of oxygen. This compound may be prepared by precipitating a solution of protosulphate of iron, by a caustic alkali, and carefully filtering; but it is impossible to obtain it in the dry state by this method, from its affinity for oxygen. It may be said that protoxide of iron does not exist in a separate state in nature; its composition is—

	Centesimally.
Oxygen,	8
Iron,	27
	35
	100·00

Magnetic Oxide of Iron.—When the protoxide combines with more oxygen, it does not pass at once into the highest state of oxidation, but into a mixture of protoxide and sesquioxide, which is permanent and magnetic, and is hence termed magnetic oxide. This compound, when found as a mineral, has a black color, and is hard. It exists abundantly in nature in different rocks; in granite, mica-slate, clay-slate, syenite, hornblende, chlorite, and also in some of the limestone formations. Much of it is found in the Island of Elba, and it has been obtained from that island for making iron from the earliest times. It also abounds in the United States of America; and mostly all the Swedish iron is manufactured from the magnetic oxide. This ore occurs in crystallines, of which the primitive is a cube: its general forms are the octahedron and dodecahedron. Its density varies from 5·00 to 5·10; it fuses before the blowpipe with difficulty. In powder it is perfectly soluble in warm hydrochloric acid. Its chemical composition is—

		Centesimally.
3 Eqs. iron,.....	81	71·68
4 Eqs. oxygen,.....	32	28·32
1 Eq. magnetic oxide,..	113	100·00

corresponding to the formula Fe_3O_4 , or $\text{Fe}_2\text{O}_3 + \text{Fe O}$. The last is considered to be the true formula, expressing a combination of one equivalent of sesquioxide and one of protoxide. The analyses obtained of magnetic oxide of iron give—

Iron,.....	71·86	71·91
Oxygen,.....	28·14	28·09
	100·00	100·00

Specular Iron Ore—Red Hematite.—This is a sesquioxide of iron existing in great abundance, and found in a variety of shapes, both massive and in crystals. The following are a few of the crystalline forms in which it is found—Figs. 272, 273, 274. The crystals are of

Fig. 272.

Fig. 273.

Fig. 274.

a dark steel-grey color, but leave a reddish-brown streak upon a stone or any hard substance; they have a specific gravity varying from 4·8 to 5·3; and are a pure sesquioxide, composed as follows:—

		Centesimally.
2 Eqs. iron,.....	54	69·34
3 Eqs. oxygen,.....	24	30·66
	78	100·00

This same oxide exists in a variety of other forms, such as a fibrous mass, with the fibres radiating from a centre, in which state it is termed the *red hematite* or *fibrous iron ore*. When the ore is an amorphous mass, it is termed *compact iron ore*; when mixed with clay and other earthy matters, *red ochre*; when hard, and combined with silica, *jaspers ore*; when in scales of a black metallic lustre, it is known as *micaceous iron ore* or *iron glance*.

This ore occurs both in the primitive and secondary rock; it abounds in the Island of Elba, Norway, Sweden, and Switzerland. Fine specimens are met with in the fissures of rocks in the volcanic districts. The red hematite, found in masses, having an unctuous feel, and readily soiling the fingers and everything with which it comes into contact, exists in many parts of England, particularly in Cornwall and Ulverston. This variety has generally from eight to ten per cent. of

silica. It is wrought in great quantities along with poorer kinds of iron, and produces a strong metal. When subjected to a high heat alone, such as the jet of the blowpipe, it yields a portion of its oxygen, and is converted into the magnetic oxide. It is very slowly soluble in hydrochloric acid. The following are several analyses of this ore from different localities:—

Iron,.....	70·42	70·27	69·85	69·22	69·	68·96
Oxygen,..	29·58	29·73	30·15	30·78	31·	31·04
	100·00	100·00	100·00	100·00	100·	100·00

Another form of the same oxide, in combination with water, is very abundant as a mineral known as *brown iron ore*. It has a brownish color, produces a yellow streak, and, when crushed, a yellow powder; it is thus easily distinguished from the anhydrous oxide, which yields a red-brown powder. It is of lower specific gravity than the red, varying in density from 3·8 to 4·2. It usually occurs in a massive state, and is composed of—

		Centesimally.
4 Eqs. iron.....	103	59·0
6 Eqs. oxygen.....	48	26·3
3 Eqs. water,.....	27	14·7
	183	100·0

This corresponds to the formula which is always given for the ore, $2\text{Fe}_2\text{O}_3 + 3\text{HO}$. The following are the results of three analyses:—

Peroxide of iron,..	80·25	90·53	86·34

Loss,.....	1·00	—	—
	100·00	100·00	100·00

Brown iron ore is found both in amorphous masses, and in crystals of a variety of forms, according as the ore may have been produced either by the decomposition of iron pyrites, or substitution and oxidation of carbonate of iron. It also occurs in small rounded pieces, either loose or conglomerated, in which state it is known as *pea iron ore*. When mixed with clay and other earthy matters, and of a soft texture, in which state it is found in great beds, it is termed *yellow ochre*. It exists in great quantities in Normandy, Berry, Lorraine, Burgundy, and constitutes the principal supply of ore for many of the French ironworks.

BOG IRON ORE.—This ore is amorphous, having a vitreous lustre, yellowish and dark-brown in color; it is of very recent formation, and is produced from the decomposition of certain rocks over which water passes; it is therefore always found in low marshy places, and hence its name. The following are the results of analyses of this ore from different localities:—

Sesquioxide of iron,.....	78·57	43·4	66·0	66·33	51·0	70·05

	100·00	99·6	98·5	100·00	100·40	100·00

IRON PYRITES.—The affinity between iron and sulphur is equal to that between iron and oxygen, varying according to the circumstances in which they are placed; under one condition, oxygen will take the iron from the sulphur, and again, under other circumstances, iron will leave the oxygen for the sulphur. That these conditions may have determined the different combinations in nature is a probable hypothesis. Sulphur and iron are combined in a great variety of proportions, and give rise to an important series of minerals, the most abundant being what is termed iron pyrites or bisulphide of iron. This mineral varies in tint, according to its exposure, from a yellow bronze to a silver white; the high bronze yellow hue may be familiar to every one in what is termed the sulphur in coal, which is iron pyrites; it has a metallic lustre, and is very hard, being capable of striking fire with steel, and therefore occasionally termed firestone; it is very brittle, and has a specific gravity of from 4·8 to 5·1. It occurs in beautiful cubical and octahedral crystals, some of which are represented by the following figures.

Different localities are known to give pyrites with a certain definite form of crystal peculiar to each, as for

Fig. 275.

Fig. 276.

Fig. 277.

instance, the Island of Elba, which yields pyrites in crystals extremely large, and often of a pentagonal dodecahedron form, while some of the Cornish mines abound more in cubical crystals. A familiar instance of this form is seen in the common slate, and is popularly termed, *slate diamond*; these are true cubes of iron pyrites. The composition of this mineral is:—

		Per cent.
1 Eq. of iron,	27	45·76
2 Eqs. of sulphur,	32	54·24
	59	100·00

expressed by the formula Fe S_2 .

The various analyses of this mineral have given a composition which exhibits the following relations to the theoretical numbers above indicated:—

Iron,	47·85	46·08	46·53	46·5
Sulphur, ..	52·15	53·92	53·39	53·5
	100·00	100·00	99·92	100·0

Pyrites is very widely diffused through rocks. It has not yet been used as a source of supply for the manufacture of iron, but is most extensively employed for the making of sulphuric acid and alum—see Vol. I., p. 156. The residue of the heaps in making acid or alum is a sesquioxide of iron, with some remaining sulphur and earths, and is used as a coarse pigment for out-door purposes, under the name of *colcothar* or *purple brown*.

There is a certain kind of pyrites very common

in the mineral districts, and found in round and sometimes curiously-shaped nodules in clay, which when broken has a radiated appearance of fibres proceeding from the centre, or sometimes from various centres, and is often either compact or granular. This sort is termed *white pyrites*, it being lighter in the color. It is also termed *cockscomb pyrites*, from its radiations. It has a density varying from 4·69 to 4·90. When analysed it is found to have the same composition as the other sort, but is much more liable to spontaneous decomposition. When exposed to a damp atmosphere, it often crumbles to pieces; the sulphur is oxidised and converted into sulphuric acid, which combines with the iron to form sulphate of iron or copperas, and appears as an efflorescence of minute crystals on the surface of the mineral. This sort of pyrites is very plentiful in Anglesea and several of the copper mines of this country. White iron pyrites is more liable to be impure than the ordinary kind, and when found in mines of other metallic ores, it is often impregnated with some of the other metals. That of Anglesea often contains both copper and zinc, and frequently small portions of silicious and argillaceous matter. A specimen analysed by BERZELIUS gave:—

Iron,	45·07
Sulphur,	53·35
Manganese,	·70
Silica,	·80
Loss,	·08
	100·00

Magnetic Iron Pyrites.—This is a sulphide distinct from the common pyrites. It is found mostly in masses filling up fissures of rocks, is seldom crystallized, and is not very abundant. Occasionally it is met with associated with common pyrites, but is distinguished from the latter by being of a deeper color, and also, as its name implies, magnetic. It has a density of 4·6, and is composed of—

		Centesimally.
7 Eqs. of iron,	189	59·63
8 Eqs. of sulphur,	128	40·37
	317	100·00

represented by the formula, $\text{Fe S}_2 + 6 (\text{Fe S})$, which expresses a combination of bi- and proto-sulphide of iron.

The following are several analyses of this mineral which agree with the formula—

Iron,	59·29	56·38	59·61	59·72	59·8
Sulphur,	40·71	43·62	40·43	40·32	40·2
	100·00	100·00	100·04	100·04	100·0

Another iron pyrites is also found, which differs little from the common, except in the form of crystal; generally, however, it has a little of another matter in it, which is present more as an impurity than as forming a part of its constitution. This mineral is known as *marcasite*, and its composition by analyses is—

Iron,	45·07	45·60	45·66
Sulphur,	53·35	53·05	54·34
Manganese, ..	0·70	—	—
Copper,	—	1·41	—
Arsenic,	—	0·93	—
Silica,	0·80	—	—
Loss,	0·08	—	—
	100·00	100·99	100·00

ARSENICAL IRON PYRITES—Mispickel.—This mineral is met with abundantly in Cornwall and upon the Continent. It is often associated with other metals, as tin. It is found in crystals, but more generally as an amorphous mass. It has a grey, silver-white color and metallic lustre, is very hard, and has a specific gravity of from 5·7 to 6·2. It is easily known from the strong smell of garlic it emits when struck by the hammer or rubbed on anything hard or heated. It is a combination of sulphur, iron, and arsenic, and is composed of—

		Centesimally.
2 Eqs. of Iron,.....	54	33·54
2 Eqs. of Sulphur,.....	32	19·87
1 Eq. of Arsenic,.....	75	46·59
	161	100·00

agreeing with the formula $\text{Fe S}_2 + \text{Fe As}$.

Another variety of arsenical pyrites is known under the technical name *Danaite*, differing from the above in having cobalt as a constituent. Its analysis from different localities does not vary much, as the following two examples show:—

Iron,.....	26·54	33·28
Cobalt,.....	8·31	6·52
Sulphur,.....	17·57	18·02
Arsenic,.....	47·55	41·86
Loss,.....	·03	·32
	100·00	100·00

Besides the few which have been described, there are several other sulphides of iron well known to mineralogists, either from their peculiar form of crystal or the state in which they are found combined. There are likewise a great variety of other minerals, being combinations of iron with other metals, as cobalt, nickel, *et cetera*; also with other matters, forming arseniates, silicates, and the like, some of which will be noticed in another part of this article. Amongst these may be specified copper pyrites, composed of copper, iron, and sulphur, but which is never wrought for the iron it contains, although yielding more of it than the ore which is generally worked for that metal.

CARBONATE OF IRON.—This is the most common ore of this country, from which the greater part of the iron is manufactured, and of which there are several varieties. The true carbonate, or *spathose iron ore*, often occurs crystalline, generally in well-shaped six-sided prisms, and rhombohedrons, similar to carbonate of lime; although more generally the ore is obtained in a massive state, with a foliated structure. It is mostly of a light-brown or grey color, having a pearly lustre, varies in specific gravity from 3·0 to 3·85, and is composed of—

		Centesimally.
1 Eq. protoxide iron,.....	35	61·4
1 Eq. carbonic acid,.....	22	38·6
	57	100·0

It is, therefore, represented by the formula Fe O, CO_2 .

This mineral, however, often contains small portions of manganese and earthy matters, as the following analyses of samples from different localities will show:—

Oxide of iron,....	53·06	49·61	59·63
Carbonic acid,....	38·41	38·44	38·04
Manganese,.....	4·20	0·10	1·89
Magnesia,.....	2·26	5·18	—

Silica,.....	0·48	—	—
Loss,.....	·47	—	—
	100·00	100·00	100·76

The most of the ores from which British iron is made consist of a carbonate found in beds in the coal formation, often alternating with the seams from which the coal is taken. This circumstance gives great facility to the manufacture of iron in this country, and is at once the cause of the superiority and cheapness of the metal. The great deposits of this kind of iron ore in Britain are those of Dudley in England, those of Wales, and of Lanarkshire and Ayrshire in Scotland. These ores are always massive, and generally contain several impurities, which, if not extracted, affect more or less the quality of the iron. They may be divided into two sorts:—

The first is the argillaceous or *clay-band* ores which contain a considerable quantity of earthy matter or clay, and these, when wrought by themselves, yield a weak and inferior quality of iron. They have a dark-grey color, nearly black, and a specific gravity varying from 3·17 to 3·41. The following analyses give a fair average of their composition taken from different districts:—

Protoxide of iron,....	32·22	38·80	35·0
Carbonic acid,....	32·53	30·76	25·5
Manganese,.....	—	0·07	0·3
Lime,.....	8·62	5·30	—
Magnesia,.....	5·19	6·70	1·6
Silica,.....	9·56	10·87	26·5
Alumina,.....	5·34	6·20	11·8
Sesquioxide of iron,....	1·16	0·33	—
Carbon,.....	2·13	1·87	—
Sulphur,.....	0·62	0·16	—
Loss,.....	2·63	—	—
	100·00	101·06	100·7

Black-band.—The second variety of this kind of ore, which is known as *black-band*, was for a long time unknown, and was first pointed out by the late D. MUSHET. It differs from the clay-band in having less earthy matters, and being much blacker in color. Some kinds of this ore have a homogeneous appearance, while others have coaly seams running between, and round light-brownish matter, stratified or in nodules; the whole mass or seam of this sort being of a mixed brown and black. The following analyses of a few samples of black-band exhibits the difference between it and the clay-band or argillaceous carbonate:—

Protoxide of iron,....	49·4	49·6	46·6
Carbonic acid,.....	35·2	30·4	30·1
Magnesia,.....	4·0	8·1	—
Alumina,.....	1·8	1·8	—
Lime,.....	—	—	6·3
Silica,.....	—	—	5·4
Coaly matter,.....	9·6	9·6	8·4
Loss,.....	—	0·5	3·2
	100·0	100·0	100·0

This class of ore is exceedingly valuable to the manufacturer, as the presence of the coal assists in some of the preliminary operations. These two ores, the

black and clay band, are generally wrought together, and give iron of excellent quality.

A most valuable addition to our knowledge of the iron ores of the Northern and North Midland Counties of England has been recently given to the world, in the *Memoirs of the Geological Survey of Great Britain*. These are to be further extended, and the completion

of the work will be hailed as a great boon by chemists and iron manufacturers. At the same time, unless these analyses of the ores be followed up by a similar investigation into the flux and fuel used, and the iron produced from the ores, the directors of the Museum of Practical Geology will only tantalise the manufacturers by an unfinished work:—

OVERMANN has the following remarks on the clay-band of America:—

The compact carbonate of iron, sphaerosiderite, argillaceous iron ore, has no relation externally with the sparry variety; it comprehends most of the clay ironstones of the coal measures, particularly those which occur in flattened spheroidal masses, varying in size from the dimensions of a small bean to pieces weighing a ton. The color of this ore is commonly a dirty blue or grey-brown, reddish-brown, and yellowish-brown; fracture close-grained, hard, streaked white or brown, blackens before the blowpipe, and if calcined, is attracted by the magnet. This carbonate of iron, though belonging to the coal formation, is found in various places in the tertiary strata. It is the principal ore from which iron is smelted in England and Scotland, and yields usually from thirty to thirty-three per cent. of iron. It is largely distributed over the United States—Pennsylvania abounds in it. It exists in Maryland, Virginia, Ohio, Illinois, North Carolina, and Kentucky. The difficulty of working this kind of ore in the blast furnace, may be assigned as the reason why it is not more generally employed. England and Scotland use it extensively, and work scarcely any other kind.

VALUATION OF IRON ORES.—The value of the ore depends upon two conditions:—first, the quantity of iron it contains, and, second, the amount of impurities or matrix. The character and properties of the impurities, and the extent to which they will interfere with the quality of the iron when manufactured, must also be considered. To ascertain these points, the ore must be subjected to testing or assaying. There are two methods of assaying, termed respectively the wet and dry.

Wet Method.—What is termed the wet assay is the most accurate, and may be performed by any ordinary operative, after a short experience. Although, in the first instance, the operator wishes only to ascertain the quantity of iron in the ore, still, that being only a part of the process for obtaining the whole of the ingredients, it will be better to describe here the complete analysis required for practical purposes. The mineral being ground, weigh fifty grains and put them into a flask or beaker; add pretty strong aqua regia, and then digest the whole on a sand-bath at a boiling heat for fifteen or twenty minutes; remove the vessel from the heat, and add a little water; after allowing it to stand several minutes, decant the clear

solution; add to the undissolved residue as much acid and water as at first, and repeat the digestion; then put the two solutions together, pour the whole into a porcelain basin, and evaporate to dryness; next add two ounces hydrochloric acid, and two ounces water, digest for ten minutes, and pour the whole upon a paper filter, taking care not to lose any of the liquid; wash the residue upon the filter till the liquor passing through is free of acid; dry the filter, heat the contents in a crucible to redness, and then weigh. This gives the insoluble matter. The filtrate is now carefully divided into two equal proportions; to the one is added caustic ammonia in excess, and then filtered; the contents of the filter are well washed, and then dried; the liquid filtered through with the washing is to be kept. To the other half of the solution add caustic potassa till the iron is precipitated, then add a considerable excess, and boil the whole for ten minutes, filter while hot, and wash the precipitate with warm water till the alkali is all removed; the iron precipitate is then dried. These two iron precipitates are now heated to redness in a crucible, and weighed separately; the weight of the one obtained by potassa will be that of the sesquioxide of iron; the weight of the other will be the sesquioxide of iron and alumina, if any of that substance has been dissolved; the difference of weight will therefore indicate the alumina, which is noted down. The quantity of iron which the sesquioxide contains is known by calculating their equivalents, which are as ten to seven:—thus, if the sesquioxide obtained be 12·5 grains, then $10 : 7 :: 12·5 : 8·75$, and this being in twenty-five grains, will make the percentage of the ore thirty-five.

To the solution filtered from the precipitate by ammonia, there is added oxalate of ammonia, so long as a precipitate is formed, if there be any; this is stirred well, and after heating the solution it is again filtered, and the precipitate washed and dried. This is the lime in the state of oxalate, which is converted into carbonate of lime by subjecting it to red heat in a crucible, and then weighed. As the carbonate is the condition in which the lime would exist in the mineral, no calculation is required. To the solution filtered from the lime is added a little solution of phosphate of soda; the mixture is well-stirred for seven or ten minutes, and then allowed to stand for an hour; if a precipitate is formed, it is filtered, well washed, dried, and burned at a red heat; this precipitate is the phosphate of magnesia. When burned and washed, the quantity of magnesia present in the mineral is known from the fact, that every 237 parts of the precipitate are equal to 85·4 magnesia.

When the ore is to be tested for sulphur, it is better to take a separate portion of the mineral—say twenty-five grains—and digest in two parts hydrochloric and one nitric acid, for half an hour, then dilute and filter, and add to the filtered solution chloride of barium—allow it to stand for an hour; any precipitate formed is sulphate of baryta, which is obtained by filtering, washing, and then drying and burning; every one hundred and sixteen parts of this precipitate is equal to sixteen parts of sulphur. If only the quantity of iron be required, then the operator need go no further than the first

precipitate, but he will have to take potassa only, and proceed as directed above.

The preceding method is applicable to any of the ordinary classes of iron ore, such as the hematite, brown oxide, magnetic, *et cetera*. Sulphides are never used for the manufacture of the metal; but even these, such as the common pyrites, may also be tested in the same way.

A few years ago Professor FUCHS recommended, for ascertaining the value of iron ores, the following process, founded upon the fact that copper reduces sesquioxide of iron to the state of protoxide:—Take fifty grains of the powdered ore to be operated upon, and digest in strong hydrochloric acid till all the iron is dissolved—say about half an hour; then add by degrees about twenty-five grains of chlorate of potassa to oxidise the iron—neither nitric acid nor nitrate must be used for this purpose. When the iron is oxidised, the solution is brought to boil, then a clean slip of pure copper is added, which must have been previously weighed, and the solution is kept in ebullition to prevent access of air. After ten minutes' boiling, and previous to removing the undissolved copper from the solution, hot water is to be added till the vessel is quite full; this is to be poured off, and the vessel again filled with fresh hot water. The copper, which is generally covered with a brownish coating, is then carefully washed in cold water, dried at a gentle heat, and finally weighed; every four grains of copper dissolved indicates five grains of sesquioxide of iron present in solution; the quantity of metallic iron may then be calculated as already stated.

The advantages of a process of this kind are not only that it is simple and easy to perform, but the presence of any of the earthy matters, as silica, lime, alumina, or other metals, does not interfere with it; only, if the ore contains arsenic, this process will not answer. Much care must be taken not to prolong the operation, as copper is dissolved by the acid present in small quantity, and in that case the results cannot be relied on; yet many are able from experience to perform the analysis in this way with great accuracy.

Another simple process for testing the quantity of iron in an ore, based upon the reaction of the protosalts of iron upon permanganate of potassa, has been proposed by MARGUERITE:—When a solution of permanganate of potassa is poured into a very dilute acid solution of protosalt of iron, the protosalt becomes converted into the sesquioxide at the expense of the oxygen of the permanganate, decoloring the solution. As long as any protosalt of iron remains, it is immediately decomposed in proportion as the solution of the permanganate is gradually poured into it, the liquor assuming a very pale yellow color, due to the sesquioxide of iron produced; but as soon as all the iron is oxidised, one single drop of permanganate suffices to impart a distinct pink color to the liquor, which indicates that the experiment is finished.

Permanganate of potassa is prepared as follows:—

	Parts.
Binoxide of manganese,.....	2
Chlorate of potassa,.....	1
Caustic potassa,.....	3

Mix the whole thoroughly, introduce the mixture into

a Hessian crucible, and keep it at a low red heat for about two hours. The mass, which is of a dark-green color, is then reduced to coarse powder, and mixed with three or four times its weight of water; after stirring the whole, nitric acid, diluted with half its weight of water, is gradually added until the liquor assumes a fine violet color; it is then filtered through pounded glass or asbestos, and preserved in a glass-stoppered phial. The reason of filtering through asbestos or glass is because contact with organic matter, such as paper or linen, decomposes the permanganate. The salt is very stable, and may be preserved for a long time without alteration, provided always that it be kept in a glass-stoppered bottle, and contact with dust or any organic matter carefully avoided.

To make the permanganate of the proper strength, dissolve twenty-five grains of pianoforte wire—which may be considered pure iron—in about 1·500 grains by measure of pure hydrochloric acid. When dissolved, and the disengagement of hydrogen gas has ceased, dilute the solution with about one pint and a half of water. It is necessary to dilute the solution to this extent, and to operate in the cold, in order to guard against the excess of hydrochloric acid reacting upon the permanganate and disengaging chlorine; one thousand grains-measure of the solution of permanganate of potassa, prepared as before described, being introduced into an alkalimeter, it must now be gradually poured therefrom carefully, drop by drop, into the hydrochloric acid solution of iron just alluded to, stirring the liquor all the time in order to insure complete action, exactly as in alkalimetry.

On adding the solution of permanganate of potassa, the operator will perceive that, at first, it is decolorized as fast as it is poured in; but the rapidity of action gradually diminishes, and, at last, it imparts to the liquor a pinkish tint, which indicates that the whole of the iron in the liquor is oxidised. The number of divisions which have been required to obtain that result is carefully observed; and supposing, for example, that fifty divisions of the alkalimeter have been required to oxidise the twenty-five grains of pianoforte-wire employed, it is evident that each division of the permanganate of potassa test-liquors represents half a grain of metallic iron.

But whatever may be the strength of the solution of permanganate, it is always easy to adjust it to any desired standard; if too weak, by concentrating it by evaporation at a gentle heat; if too strong, by diluting it with a suitable quantity of water, so that it may be brought as near as possible to such a strength that one measure of the alkalimeter may indicate half a grain of metallic iron.

Take twenty grains of the iron ore and reduce them to very fine powder by levigation; put them into a flask capable of holding about a quart of water, and pour into it about one thousand grains-measure of pure and fuming hydrochloric acid. The mixture is now moderately boiled until the ore has dissolved. Water is then poured in, so as to fill up about one-third of the flask; and the salt of iron is brought entirely to the state of protosalt, by adding about one hundred grains of pure zinc, or about sixty grains of sulphite

of soda. After boiling for a few minutes, and as soon as the liquor no longer evolves an odor of sulphurous acid, and has become greenish or almost colorless, all the iron has passed into the state of protosalt. The solution is then diluted with a fresh quantity of water, so as almost to fill the flask, and the test-liquor of the permanganate of potassa is poured in, drop by drop, until the characteristic pink color is produced. The operator then reads off the number of divisions employed.

Let it be supposed, for example, that the test-liquor is of such a strength that each division represents half a grain of pure iron, and that twenty-two divisions have been required to oxidise the metal contained in the twenty grains of ore operated upon. It is evident that these twenty grains contain eleven grains, and consequently fifty-five per cent. of iron.

This process is obviously much more rapid than any of those previously described, and the presence of any other metal or earth does not interfere with the results—except two, namely, arsenic and copper. Should either of these be present, they may be separated, previous to applying the test, by a bar of zinc, which precipitates them. Then filter the solution, and proceed as described.

The Dry Method.—By the preceding methods, it will be observed that it is the quantity of pure metal that is estimated; whereas, by the process of smelting, the metal is not obtained pure. Some metallurgists prefer using a process more analogous to the smelting operations for testing the value of the ore and the quality of the iron, and for this purpose practise what is termed the dry assay; this is performed by taking a sample of the ore and fusing it in a crucible, to obtain the iron in the metallic state. It will have been observed, that the ores generally contain small portions of silica, alumina, *et cetera*. Such matters are by themselves infusible; but at a high temperature they combine with the oxide of iron, and form a fusible compound; so that were the ore put into a crucible alone and fused, iron would not be obtained, but a combination of oxide of iron. It is necessary, therefore, to mix with the ore some matters that will combine with the substances named, and set the iron free. Such are termed fluxes and reducing agents; but even by the aid of these, the operation of assaying by the former requires great care, and necessarily a very high heat, the apparatus and operations for which are as follow.

The common assay furnace is of a very simple form. It is generally constructed upon the floor of the room, close to where there is a chimney, so as to insure a good draught. The following sectional sketch—Fig. 278—will give the best idea of its construction. A is the fire-place containing two crucibles; B, the chimney; c, ashpit open from the front for the admission of air; d, the grate bars; ef, cover for fire; g, damper for regulating heat.

The grate bars are loose pieces of bar-iron half an inch square, leaving an intervening space of the same size, and laid loose, so that they may be removed and the fire-place cleaned out, as the coals and bricks are apt to cake and choke up the fire-place. The latter should be lined with the best fire-brick built in with fire-clay,

and should be from sixteen to eighteen inches square, and from twenty-four to thirty inches deep. The fire is fed from the top, which is covered by a fire-clay

Fig. 278.

tile, furnished with a rim of iron. The whole furnace should be strapped round with belts of iron, to prevent its splitting or falling to pieces by the expansion; or a very common method, and the most secure, is to fit them round with a cast-iron casing, which is a great preventive against the furnace rending and admitting currents of air. The most suitable fuel is a mixture of coal and coke. The furnace should be at a good heat before the crucibles are put into it. Some assayers place a small piece of tile or brick upon the bars on which the crucibles stand, while others embed them in the fire, which is the best method for obtaining an equal heat round the crucible. In a furnace of the size stated, two or three crucibles may be placed in the fire at a time, and this is often recommended; but the Editor prefers to use only one at a time, as giving the most certain results, though requiring a little longer for the operation. The most refractory kind of crucibles should be used; those termed the Cornish and Hessian answer very well. A good assortment of them, laid in a warm place, should be kept on hand by the assayer. Covers are also prepared for them, by baking a piece of fire-clay into the required shape and size.

For the purpose of inserting or removing the crucibles from the furnace, a number of different-shaped tongs are wanted. There are also required the following fluxes and reagents—pounded charcoal, slaked lime, potassa and soda, tartar, borax, and ground glass. If the assayer has a knowledge of chemical operations, he will, before making an assay, ascertain by means of tests, as already referred to, an approximate idea of the quantity of lime, silica, and alumina present, so as to regulate his fluxes; but it often happens that the assayer is ignorant of this, and he consequently judges of the quality of the ore and the fluxes to be used by the appearance of the ore when ground and burned. The assay is then proceeded with, by first taking a sample of the ore and grinding it fine in an iron mortar, weighing out two hundred grains, and placing it, mixed with an equal quantity of dry slaked lime and fifty grains of powdered char-

coal, upon a clean piece of glazed paper; but if the ore be a refractory one, a little carbonate of soda or potassa may also be added.

The crucible should be previously prepared by filling it with pounded charcoal, moistened with water; this should be pressed into the crucible, and dried. A hole is scooped out in the centre of the charcoal, so as to leave about one quarter of an inch of charcoal all round. The mixed ore and flux are put into this cavity; the crucible is covered and luted with clay, and then placed in the centre of the furnace, the fire of which should have been allowed to burn low. When the crucible is properly embedded, coal and coke are packed all round and over it, filling the furnace nearly to the top; the crucible being as nearly as possible in the centre of the fire. For a time the fire is allowed to burn slowly, so as to drive off all damp from the ore and crucible. After a while the fire is covered, and the heat raised to the highest pitch and continued for about half an hour, when the cover of the furnace is removed, and a portion of the fire is taken out from the top, to expose the crucible, which is then withdrawn by a pair of tongs, giving it a gentle tap upon the floor, to shake down any particles of fused metal. When cool, the lid is taken off and the contents examined. For this purpose the crucible is generally broken; if the temperature has been sufficient, a small button of metallic iron will be found under the slag; if the heat has not been high enough, or a proper supply of flux has been wanting, the slag is full of small metallic beads, or the whole forms an agglutinated mass; in the latter case, the only remedy is to repeat the operation. If the process is successful, the small button of iron is carefully detached and hammered, to drive off any scoria adhering. The success of the whole operation is judged of by the appearance of the slag; it should be a greenish or greyish glass. This should be ground fine and spread upon paper, and a magnet drawn over it to detect any little prill of iron which may have remained in the slag. The whole iron is then weighed and the per-centage calculated. Iron thus obtained is not perfectly pure, but in general it is as pure as cast-iron, and may therefore be taken as the true valuation, if cast-iron is to be made from the same ore.

MUSHET, in his work upon iron and steel, enters extensively into the assaying of different ores by the furnace; he arranges the ores for assay into three classes—*argillaceous*, *calcareous*, and *silicious*—according to the earthy matters that prevail, so that there may be a proper distribution of flux, and each class is divided into two varieties, as follows:—

	First variety.	Average proportion.	Second variety.	Average proportion.
<i>Argillaceous iron ore</i> ,	Clay,	9	Clay,	10
	Lime,	6	Silica,	7
	Silica,	3	Lime,	3
		18		20

For every four ounces troy of this class of ore, he recommends as flux the following ingredients well mixed:—

	First variety Ounces.	Second variety. Ounces.
Bottle-glass,	4	4
Chalk,	3	4
Charcoal,	0.50	0.75

Second class of ores:—

	First variety.	Average proportion.	Second variety.	Average proportion.
<i>Calcareous iron ore</i> ,.....	Lime,.....	14	Lime,.....	10
	Clay,.....	6	Silica,.....	6
	Silica,.....	4	Clay,.....	4
		24		20

The flux recommended for this class is—

	First variety. Ounces.	Second variety. Ounces.
Bottle-glass,.....	5	4
Chalk,.....	1.50	2
Charcoal,.....	0.75	0.50

Third class of iron ores is—

	First variety.	Average proportion.	Second variety.	Average proportion.
<i>Silicious iron ore</i> ,.....	Silica,.....	12	Silica,.....	10
	Lime,.....	8	Clay,.....	7
	Clay,.....	5	Lime,.....	5
		25		22

Flux recommended for four ounces of ore:—

	First variety. Ounces.	Second variety. Ounces.
Bottle-glass,.....	3.50	3.50
Chalk,.....	3	2.50
Charcoal,.....	0.75	0.50

For hematite and such like ores that contain small portions of silica, the best flux for four ounces is—

	Ounces.
Chalk,.....	1.50 to 2
Charcoal,.....	0.50

Many assayers use slaked lime alone; others add with the lime small portions of the alkaline carbonates, or borax, which often facilitate the fusion, especially with such ores as contain much silica and alumina, and are, consequently, very refractory.

The button of iron obtained in the assay is subjected to the following test:—It is placed between a fold of thin tin-plate, to prevent it flying away on being struck, it is then hammered upon an anvil and broken; if the button flattens before breaking, and the fracture have a greyish appearance, the quality is considered good;

Fig. 279.

but should it split on the first blow of the hammer, and show a crystalline fracture, whitish in appearance, it is not good, and the ore is judged unfit for the best quality of iron.

MANUFACTURING OPERATIONS.—Iron is produced for the purposes of the arts in three different states—as *crude* or *cast-iron*, *steel*, and *malleable* or *bar-iron*. These three modifications are the results of several and separate operations, undertaken for the express purpose of obtaining the quality of iron desired; although, when each is tested separately, they are found to differ only in the quantity of carbon or charcoal in their composition. Malleable iron is the purest, and has very little carbon in it; to have it quite pure is the aim of the manufacturer, but this is never accomplished in practice. Steel contains more carbon than bar-iron, and cast-iron generally more than steel; but there is no fixed proportion of that ingredient in either by which a line may be drawn between them; they seem to merge into one another, so that some kinds of steel may be called cast-iron, and some cast-iron may be considered steel. The difference is often more dependent upon the mode in which the carbon is combined with the iron, than on the exact quantity present. Ordinary crude or cast-iron contains, also, other impurities, as silica, which render it very inferior; and the variable amount of silica and carbon found in different kinds, gives rise to a great variety of qualities of cast-iron, distinguished by technical names, such as *grey*, *mottled*, *white*, *silver*, *et cetera*.

The manufacturing operations succeed each other in the following order:—1. The calcination of the ores, by which the carbonaceous and volatile matters are burned off, and the whole reduced in bulk to prepare them for the smelting furnace; 2. The extraction or reduction of the metal in the form of cast-iron by smelting; 3. The conversion of the cast-iron into malleable or wrought iron by puddling and rolling; and 4. The reconversion of the comparatively pure malleable iron into that particular carbide which is known as steel.

CALCINATION OF THE ORES.—The carbonated ores of this country are generally prepared for the blast furnace by a process of calcination which burns away all volatile matters, and concentrates the metal. For this purpose the ores are accumulated in large heaps, generally in an open field, and mixed with carbonaceous matters, such as small coal. Some of the black bands have sufficient coal in their composition to effect their calcination. After a heap of several hundred tons is collected, a fire is kindled at the windward end, which gradually passes on through the whole mass and burns for several days, producing a very high heat, often sufficient to reduce and fuse some of the metal, which, however, is not desirable.

The black-band iron ore, of the average of thirty-three per cent. of iron, will contain, after calcination, an average of seventy per cent. of iron. The clay-band of thirty per cent. of metal in the ore, will, when properly calcined, contain about fifty-four per cent., so that by this means a great saving is effected in the amount of fuel required for the subsequent operation of smelting.

Instead of roasting the ore in open heaps, the same operation is sometimes performed in kilns, similar to those used for burning lime. In some districts, this method is found more convenient than large open heaps, covering often several hundred square yards.

SMELTING THE ORES.—The next operation is the smelting or reduction of the calcined ore, and the first subject which falls to be considered under this head is the form and *matériel* of the furnace.

The structure of the blast furnace varies considerably in different localities, according to the views of the smelter and the character of the ore and fuel, but in their general features there is much sameness. Drawings will be given of a few of the forms adopted at different times and in different places; but to enable the reader to understand the references to particular parts, it may be well to introduce, in the first place, an external and sectional view of a blast furnace of modern construction. The former is shown in Fig. 279, including the sand-bed in which the metal flows, to form the pigs of cast-iron as they are taken to market. Fig. 280 is a section of a similar furnace, consisting of two courses of fire-brick, *m m m m*; between these is a

Fig. 280.

casing, *ll*, of pieces of brick, scoria, and sand. Over the whole is the external coating of thick masonry, *nn*, formed either of ordinary bricks or of stone, as is most convenient. The inside lining of fire-bricks is technically termed the shirt of the furnace; the part extending from the cross line at *B*, and running down into the crucible portion at *E*, is composed of fire-stone; occasionally fire-bricks of the most refractory sort are used for this part also. The small part at *E* is termed the hearth; the bottom is formed of a large fire-stone, supported by a mass of mason-work, having air-channels, as seen at *N*, while open arches or galleries, *p p p*,

are made below, one intersecting another at right angles, to keep the whole erection dry. D is the chimney surrounded by a gangway, with openings to admit the barrow, by which the furnaceman introduces the ore, flux, and fuel. c is the *throat* or *trunnel* hole of the furnace; A is called the cone or body; ■ the boshes; HH are arches leading through from one tuyere-hole to another, for convenience in attending upon the furnace. One of the stones composing the hearth, as shown at r, does not reach the base, but is supported by a strong bearer of iron built into the masonry, on which rests a block of sandstone called the *tymp*. Below, and a little in advance, is placed what is termed the damstone, a. The sides of the hearth are perforated a little above the level of the tymp with holes, cc, for the admission of the discharging orifices of the blowing apparatus, termed *tuyeres*; the arrangements of which will be shown in a future figure.

The preceding details will enable the reader to appreciate the points of resemblance and of difference in the following furnaces.

Fig. 281 represents a furnace which at one time was very common in Europe, and some specimens of which

Fig. 281.

still exist in Spain and Hungary. It is exactly in the form of two crucibles, the one inverted over the other. This furnace measures from ten to sixteen feet in height, two feet wide at bottom and top, and five feet in the centre; two tuyeres are seen at aa, which admit the nozzles of two pair of bellows; in the front is an opening about two feet square, which, while in work, is built up with brick. After the furnace is heated sufficiently to permit the descent of the partially-fused metal, it is charged with the ore and charcoal fuel, and this is continued till, from the quantity of ore put in, the reduced metal would be up to near the tuyeres. The blast is then stopped, the front part, or breast wall, built up with brick, is removed, and the iron, which exists in a solid mass, is loosened and removed by crow-bars, and then carried to the forge hammers and wrought up into bar-iron. The front is again built up, and the smelting operations renewed. From the state in which

the iron is obtained, this furnace has been named the *salamander* furnace.

Fig. 282 represents what is termed the *blue oven*. This kind of furnace is in common use in Germany,

Fig. 282.

and approaches near to our ordinary blast-furnace in the internal shape; its height is from twenty to twenty-five feet; a indicates the tuyere holes; it is also furnished with a breast, which can be removed; at the bottom, however, is a small hole, to let out the fluid metal; and a little above this, another to enable the scoria to be taken out. The bottom of the furnace is made to slope to the tap-hole. The fuel used is charcoal. This is considered an excellent furnace for spar-iron ore, and yields a good steel-iron.

The form of furnace used in the Hartz mountains is shown in Figs. 283 and 284. It is constructed of very

Fig. 283.

heavy masonry. The crucible portion, c, is very high and narrow, while the boshes, b, are exceedingly flat, to allow of a very large body of coal and ore; the ores in that locality being very refractory, composed mostly of red

and brown hematites and carbonates. The metal is let out from time to time in a fluid state, and is celebrated for its superior quality over most other irons.

Fig. 284.

This form of furnace is used in Prussia and other localities for smelting bog-iron ores. It differs materially from all the other blast furnaces in its internal shape; the hearth or crucible part, however, resembles that of the one last described. The height of the furnace is about thirty feet; the crucible portion at the bottom is slightly tapered, its length being about six feet, and one and a half feet wide. Iron of very good quality is made from the bog-ore in this furnace, the fuel being charcoal.

Fig. 285 exhibits the structure of a furnace used in Styria for the smelting of sparry iron ore. The total

Fig. 285.

height is about thirty-four feet; the boshes, *b*, are about nine feet, and the top and bottom about two feet six inches diameter. The blast is produced by square wooden bellows, driven by water wheels. The

VOL. II.

iron is tapped out at intervals in quantities of from two to three hundred pounds weight. Charcoal is used as the fuel, and the best quality of metal is produced in these furnaces.

Fig. 286 represents the old blast furnaces of Sweden, which were known to have produced good iron, but in

Fig. 286.

small quantity, not exceeding three tons per week. At the present time the furnaces of Sweden are similar to those used in England.

Fig. 287 shows the interior of a furnace used in

Fig. 287.

different parts of Germany, which is a very close approximation to the most improved furnaces of this country.

Fig. 288 is a blast furnace in Silesia. It is twenty-seven feet high, and is blown with hot-blast heated at the top of the furnace. The crucible portion re-

3 G

sembles some of those already given; it is seventeen inches wide at bottom, and twenty-eight inches at top; the boshes are nine feet in diameter, the mouth or top

Fig. 288.

three feet. The tuyeres are fifteen inches above the bottom stone. The ore used is the hydrated oxide of iron, and the fuel pinewood charcoal. This furnace is remarkable for the small amount of fuel required, and

Fig. 289.

the production of a very fluid metal, excellent for fine castings, and much used for the manufacture of the celebrated Berlin castings.

Fig. 289 is a charcoal blast furnace at New York; it is forty feet in height, and nine feet in width at the boshes; its hearth is six feet six inches high, and one foot nine inches wide. The ores wrought are mostly the magnetic oxide and brown hematite, with a small quantity of bog-iron ore. It produces a good quality of grey iron, very fusible. Two tons seven hundred-weights of ore, and one hundred and twenty bushels of charcoal, are required to produce one ton of cast-iron.

Fig. 290 is another charcoal furnace, representing those in use at Pennsylvania in America. The height of this furnace, says OVERMANN, is thirty-two feet, width

Fig. 290.

of boshes nine feet six inches, hearth five feet high, two feet in width at the bottom, and two and a quarter feet at top. The rich hydrates, pipe ores, fossil ores, *et cetera*, are generally used. Two tons and a half of ore produce, on an average, one ton of metal; for each ton one hundred and eighty bushels of charcoal are required. The furnaces in operation at the oldest establishments West of the Alleghany mountains, such, for instance, as the Dover furnaces at the Cumberland river, Tennessee, are almost a true copy of those in use in Eastern Pennsylvania; both require the same amount of fuel, and both yield similar results. Going further West, there is a greater amount of coal used to produce a given amount of iron. For instance, at the Alleghany and Ohio furnaces, as far down as Hanging Rock and Portsmouth, one hundred and seventy to one hundred and eighty bushels of charcoal are considered sufficient to make a ton of iron, while in Kentucky and Tennessee from two hundred to two hundred and fifty bushels of charcoal are required to produce the same amount.

Such are a few of the different sorts of furnaces, fitted up as circumstances and locality have suggested, —all of them possessing certain qualities suitable to the conditions in which the work is conducted, and

showing, what has been already stated, that the kind of fuel and ore often necessitates modifications in the furnace.

The furnaces at present in use in this country vary a little in their structure, according to the fancy of the builder, their early or recent construction, and whether originally intended for the cold or hot blast. A view of the general structure of the modern furnace has been already given—page 415. Mr. J. J. GRIFFIN, in a series of interesting models of manufacturing apparatus for lectures, exhibits one of a blast furnace, similar to those employed in the neighborhood of Glasgow, where the hot blast is used. This is represented in Fig. 291, and will be seen to differ a little from any

Fig. 291.

of the preceding, in having the body of the furnace more of a cylindrical shape.

The interior dimensions and measurement of two

well-going furnaces, of the average size and structure used in this country, are thus tabulated by Dr. URE:—

	No. 1. Feet.	No. 2. Feet.
Height from the hearth to the throat or mouth,.....	45.0	49.0
Height of the crucible or hearth,.....	6.5	6.0
Height of the boshes,.....	8.0	7.0
Height of the cone,.....	30.5	36.0
Height of the chimney or mouth,.....	8.0	12.5
Width of the bottom of the hearth,....	2.5	2.0
Width at its upper end,.....	3.0	2.5
Width of the boshes,.....	12.5	13.5
Width at one-third of the belly,.....	12.0	11.5
Width at two-thirds of the belly,....	8.5	9.5
Width at mouth,.....	4.5	3.5
Inclination of the boshes,.....	59°	52°

Materiel of the Furnace.—The bottom or hearth, which may be considered the crucible portion, or the part where the fused matters collect, is generally composed of a silicious stone found in the coal measures, termed millstone-grit, or fire stone, from its refractory character. The upper portion of the chamber is lined with fire brick.

The fire clay for making the bricks which line the furnace, and which is generally found in the same mine with the ironstone, varies very considerably in composition in different localities, having properties more or less suitable for the purpose, according to the absence of oxides, and the quantity of silica and alumina. TAYLOR, in his analysis of the rocks of the coal-measures at the Hartley pit, gives the following:—

	Fire clay.	Muscle bind.	Blue Shale.	Bituminous Schist.
Silica,.....	62.14	63.89	58.99	56.51
Alumina,.....	31.07	33.49	26.19	31.89
Oxide of iron,.....	2.24	—	10.25	7.04
Lime,.....	0.74	2.01	0.67	1.69
Magnesia,.....	0.83	0.61	1.54	0.85
Potassa,.....	2.45	—	2.34	1.38
Soda,.....	—	—	—	0.61
Loss,.....	0.53	—	0.02	0.03
	110.00	100.00	100.00	100.00

Dr. RICHARDSON gives the subjoined analysis of the principal fire clays in the neighborhood of Newcastle:—

Silica,.....	51.10	47.55	48.55	51.11	71.28	83.29	69.25
Alumina,.....	31.35	29.50	30.25	30.40	17.75	8.10	17.90
Oxide of iron,.....	4.63	9.13	4.06	4.91	2.43	1.88	2.97
Lime,.....	1.46	1.34	1.66	1.76	2.30	2.99	1.30
Magnesia,.....	1.54	0.71	1.91	trace	2.30	2.99	1.30
Potassa,.....	2.45	—	—	—	—	—	—
Soda,.....	—	—	—	—	—	—	—
Water, and organic matter,...	10.47	12.01	10.67	12.29	6.94	3.64	7.58
	100.55	100.24	97.10	100.47	100.70	99.90	98.90

Stourbridge has been long celebrated for its fire clay, which is admirably fitted for making crucibles and lining furnaces. The composition of various qua-

lities of this clay as given by different analysts, along with fire clays from several other localities, is shown in the following table:—

	Stourbridge.			Monmouth.	Pembroke.	Govan.	
	Bertlender.	Salvett.	Cowper.	Cowper.		Penny.	Penny.
Silica,.....	63.7	45.25	63.3	75.3	88.43	60.2	59.7
Alumina,.....	20.7	28.77	25.3	16.8	6.90	37.7	37.5
Oxide of iron,.....	4.0	7.72	1.8	1.0	1.50	1.0	2.3
Lime,.....	—	0.47	1.5	0.9	3.40	1.0	1.0
Magnesia,.....	—	—	trace	—	trace	—	—
Water,.....	10.3	17.34	10.3	6.0	dried	dry	dry

For the sake of comparison, analyses of a few fire clays from different localities on the Continent are here added:—

	Gross. Berthier.	Almerode. Salvetal.	Beaufoy's dep. des Ardennes. Berthier.	Schierdorf near Passau. Salvetal.
Silica,.....	46.5 ..	47.50 ..	52.0 ..	45.79
Alumina,.....	34.9 ..	34.37 ..	27.0 ..	28.10
Oxide of iron,...	3.0 ..	1.24 ..	2.0 ..	6.55
Lime,.....	— ..	0.50 ..	— ..	2.00
Magnesia,.....	— ..	1.00 ..	— ..	—
Water,.....	15.2 ..	14.43 ..	19.0 ..	17.00

In making the bricks from these clays, they lose the water and become anhydrous; so that the character of the compound is thus considerably altered. Fire clay is also used as mortar for the inside lining of the furnace, which is subject to high heat. The outside work of the furnace is constructed either of common brick or stone, according as the one or the other is most easily procured in the locality.

THE BLAST.—Having described the various forms of furnaces, it will now be necessary to refer briefly to the mode of producing the blast. It has been stated that in olden times the pit furnaces, or *bloomeries*, as they were termed, were often made on the face of a declivity, having a frontage to the sea-breeze, with a proper construction for admitting the air; but that, by-and-by, bellows were used of various forms, according to the state of the arts; and that in the last century an improvement was effected, which completely revolutionized the smelting operations by the introduction of what is termed the cylinder blast, or *blowing machine*. This is made somewhat similar to the cylinder of a steam-engine, as shown in the annexed drawing—Fig. 292.

The cylinder is made of cast-iron, accurately turned inside, and fitted with a piston, made air-tight either by packing with hemp or gutta-percha, or by a metallic spring. It is closed at both ends; but the cover is provided with an aperture for the piston-rod, stuffed

Fig. 292.

with leather or other suitable material to prevent the air from passing through. In the figure the piston is being forced down; the valve at *a'''* is open to admit

the air from the external atmosphere; while the valve, *a*, is shut to prevent it being pressed out; and the valve, *a'*, is open to allow the pressed air to pass into the chamber, B; while the valve, *a''*, is shut to prevent the pressed air returning to the upper portion of the cylinder. When the piston returns upwards, the conditions are reversed; the valves, *a'''* and *a'*, are shut, and *a* and *a''* are open; from the chamber, B, is a pipe, O, which conveys the blast to the tuyeres opening into the furnace.

To prevent the fusion of the nozzles of the pipes conveying the blast, the tuyeres are made of a hollow

Fig. 293.

mass of cast-iron of a conical shape, through which flows a current of cold water. The nozzle of the pipe is connected with the main pipe by leather bands or rings.

The tuyeres are generally three in number, entering the blast furnaces in three different parts. Care is taken, however, that although at the same level, they are not placed in such a position that the different currents should come into contact with each other in the furnace. The drawing—Fig. 293—will illustrate their position.

When cold-blast is applied, the air passes directly to the blast furnace; but when hot-blast is used, the air is made to circulate through pipes fitted into a large chamber furnace, by which the air is heated to several hundred degrees, and then admitted to the blast furnace. Fig. 294 will give an idea of the mode of heating the air in its passage from the blowing machine to the blast furnace.

The chamber in which the air is condensed by the blowing cylinder is large, and a considerable quantity of air is pressed into it, so that the blast entering the tuyeres is continuous. The pressure at which the air is thrown into the furnace varies, and smelters work with different pressures, according to the nature of the fuel employed and the season of the year. In summer a larger quantity is injected than in winter, owing to the air containing less oxygen in a given bulk in warm than in cold weather. The moisture of the air also affects the action of the blast—all which circumstances, even where the greatest care is taken,

are found to cause considerable variation in the working of the furnace. The special effects produced by

Fig. 294.

the nature and quality of the blast will be considered afterwards.

Having given a brief outline of the different forms of blast furnace and the blowing machine, it may be necessary further to mention in reference to the furnace, that when newly built, great care is required in bringing it to a heat. If the heat be raised too rapidly, the furnace is apt to crack and become damaged. A small fire is, therefore, kindled in the first place, and gradually increased till the whole building is quite dry, by which time the fire in the furnace will be at the height of the boshes, requiring for this several days; then small quantities of ore are mixed with the fuel, and this is continued until the first portions of the ore have sunk to near the tuyeres, when the furnace may be said to begin its work.

THE FUEL.—The fuel employed in the blast furnace is either charcoal, coke, or coal. It has been shown that the first was almost exclusively used until the second half of the last century, when the introduction of the cylinder blowing machine, along with the steam-engine, permitted pit-coal to be most advantageous. It is true that, when this change was introduced, considerable difficulties were experienced in working the rich oxide ores; they fused too easily, and passed down into the mass of melted iron before the whole of the oxide was reduced to the metallic state. Experience, therefore, taught the smelter to use these rich ores in small quantities only, mixing with them the earthy and carbonated ores; and a more judicious apportioning of the flux has latterly enabled him more completely to overcome the difficulty.

The nature and qualities of different kinds of fuel have been fully discussed in a separate article devoted to that subject, to which the reader is referred for some important information in connection with its application to the smelting of iron ores. It is of the utmost importance that the

metallurgist should have a thorough understanding of the nature and value of his fuel, otherwise he will be always liable to variations in the production of his furnace. There is first to be considered the intensity of the heat to be obtained from a given bulk of fuel. This will be modified to a certain extent by the nature of the blast and the shape of the furnace; but coals that have much volatile matter in them lose this at a low heat, before the caloric which it would supply can act upon the lime employed as flux. Such coals are considered weak for smelting. Fuel containing much ash is also proportionally weak. The quality of the ash must likewise be considered with a view to the question, whether it contains ingredients deleterious to the iron; and also, whether the coal or coke contains any impurity, such as sulphur, which, though not remaining in the ash, may yet combine injuriously with the iron.

When charcoal is the fuel, the only care of the smelter is economy, as far as consistent with the production of slags free from iron; for the ash or incombustible portion of charcoal is so small, and generally of such a character, as to be easily fused and taken up by the earths of the ore, so that there is little risk of any deterioration of the iron from this cause. Indeed the ash of charcoal is generally composed of such matters as form the best class of flux for the silica. In slags from the iron smelted with charcoal, there is generally nothing present but the pure silicate of lime, with a little potassa or other alkali, which may have been present in the ash of the charcoal. With coal and coke, however, the results are different. It will be seen from the analysis of coal, given under FUEL, that much of it contains small quantities of sulphur in the form of iron pyrites. Whether the coal be used raw or coked, the sulphur and the iron remain united, the sulphur being often amongst the last matters expelled by combustion, and only when the heat of the combustion is lower than will fuse the sulphide of iron; but, if higher, these will fuse together, and flow by their weight through the burning fuel, and, in the blast furnace, would mix with the iron; consequently, the presence of sulphur in the fuel is highly injurious, and ought to be carefully avoided. The ash of some coals being also considerable in quantity, constitutes a great proportion of the materials entering into combination in the furnace, either as scoria or with the metal. When fuel contains sulphur, or, as is often the case, the ore contains small portions of sulphur, a large excess of lime has to be added, which, when sulphide of iron is present and brought into contact, decomposes it, forming a sulphide of calcium, which is found in the slags or scoria. Yet, notwithstanding these reactions, the iron produced from coke and coal is seldom free from a small portion of sulphur, and is inferior to that made by charcoal.

Many processes have been tried to free the coke used for smelting purposes from sulphur. Mr. CALVERT recently proposed to apply small portions of chloride of sodium to the coke in the process of manufacture, by which means the fuel was made more suitable for the iron being freed from its sulphur, and in several experiments the iron made from this prepared coke was found much superior to the ordinary quality; but the process has not yet been very

extensively adopted. Small portions of chloride of sodium have also been applied directly to the blast furnace, being injected by the blast, with results less or more favorable in different localities where tried. Carbonates of potassa and soda in small quantity, mixed with slaked lime, have also been injected into the furnace for the same object; but nothing as yet of any real practical value has been adopted to free the iron from the sulphur which may have combined with it from either the fuel or ore. It is true that its deteriorating influence is generally considered by the smelter to be greater than that of any other impurity; but this effect is probably exaggerated, as there are other impurities common to cast-iron, which are as injurious to the quality, and are present in greater proportion than the sulphur; some of these will be considered in a subsequent part of this article.

In a paper which was read by Mr. Fairbairn before the Society of Civil Engineers, the chemical action of the chloride of sodium added to the coke was thus described:—When coal was first subjected to heat in a coke oven, the bisulphide of iron contained in the coal was decomposed into sulphur, which latter was distilled or burned, and also into protosulphide of iron, which remained in the mass, and was acted upon by the chloride of sodium, as it was volatilized at a red heat; thus chloride of iron and protosulphide of sodium were produced. Then a second chemical reaction ensued: the protochloride of iron was decomposed into a subchloride of iron, and the chlorine gas, thus liberated, reacted on the sulphide of sodium, giving rise to chloride of sodium and to chloride of sulphur, which latter was disengaged—so that the prepared coke contained less sulphur than the ordinary coke; but admitting even that a small portion remained, it would be in the state of sulphide of sodium, which would not yield any of its sulphur during combustion, but passed into the cinders of the blast furnace or of the cupola, and the sulphur, thus fixed, did not enter into combination with the iron, preventing crystallization during the process of smelting, and giving greater tenacity and closeness of texture both to the cast and to the malleable iron.

THE FLUX.—It will be seen, by referring to the different qualities of the ores of iron, that mostly all of them contain small quantities of other matters; and that when these are silica and alumina, which are the most common, either separately or together, they are infusible in the blast furnace; but at a temperature below that of melting iron, they will combine with the oxides of other metals, and form with them combinations that are fusible. The oxides of iron combine readily with silica, and form a silicate of iron which is very easily fused. If, then, a mixture of iron ore and coal be put into the blast furnace, the reactions may be represented as somewhat like the following. Suppose a mixture is taken of clay and black band, composed as under:—

Oxide of iron,	80
Alumina,	13
Silica,	7

When these materials reach a temperature in the furnace sufficiently high to fuse a compound silicate of

alumina and oxide of iron, the silica and alumina present will take up the required proportion of oxide of iron, and only the remainder of the iron will be reduced as metal, the silicates forming scoria; and thus a great quantity of the iron will be lost, varying according to the quantity of silica present in the ore. By a mixture of the iron ores above-mentioned, nearly one-third of the whole iron would be lost.

The object of the smelter is to obtain all the iron that exists in the ore. In order to effect this, it is necessary to put into the furnace, along with the ore, some matter that will combine with the silica in preference to the oxide of iron, and leave the latter to be reduced by the carbon. This must be some ingredient which can be procured in abundance at little expense, that it may not materially enhance the cost of producing the iron. The substance which best fulfils these conditions is limestone. Accordingly, in the smelting of iron on the large scale, lime is the only flux used; and fortunately it is generally found in abundance along with the ore, as the lowest bed of the coal formation in this country usually rests upon limestone. Thus, not only the ore, but the flux, and even the fuel itself, the blocks of refractory stone necessary for constructing the furnace, and the clay of which the fire bricks are composed, are often all found together—a provision calculated to excite the admiration of even the most unreflecting.

When lime and silica are subjected to a high temperature they combine easily, and form a fusible compound. The proportions in which lime and silica unite are various; but the heat required for their fusion differs according to the amount of lime present. If there is but a small quantity of lime compared with the silica, it requires a much higher temperature to fuse than if the former was in greater quantity than the latter. Taking the equivalent of silica at 46, then the weights which will be required to form a protosilicate with the following bases, are—

Slaked lime,	45
Limestone,	58
Fluor spar,	39
Carbonate of magnesia,	34
Carbonate of potassa,	69
Carbonate of soda,	53
Protoxide of iron,	36
Sesquioxide of iron,	40

When alumina is combined with the silica, forming a natural clay, a much more compact and fusible compound is formed with the lime than when the silica is alone. Indeed, it has been observed as a general principle, that the point of fusion is materially affected by the relation and number of bases the whole materials contain: thus, a more liquid scoria is obtained by the addition of a limestone containing magnesia than with a pure limestone. But experience is against the use of a magnesian limestone, because it deteriorates the iron produced, while the purity of the metal is the primary consideration. That which contains much silica should also be used sparingly, as silica combines with the iron and injures its quality.

The purest limestones are the most suitable for flux. Common marble is nearly a pure carbonate of lime; but is too rare and expensive to be used as a flux.

Chalk is another very pure carbonate, and forms a most excellent flux, but is seldom used in large operations.

Oolite limestone, which derives its name from its being composed of small round grains like the roe of a fish, is another excellent and pure carbonate of lime.

Compact limestone, grey limestone, mountain limestone, *et cetera*, are very abundant, and are found of a great variety of colors, but never so white as the preceding, as they often contain carbon and oxide of iron, which are not detrimental as a flux.

There is another family of limestones termed the swinestone, and bituminous limestone; or sometimes *stinkstone* or fetid limestone, from its giving out an offensive smell when rubbed against any hard substance. This mineral is dark in the color, owing to the carbonaceous matters combined with it, and very hard; but when burned it is white, and forms an excellent pure lime and a good flux.

The following analyses of different limestones used as flux, selected from various sources, will give the reader the best idea of their variety:—

CONTINENTAL LIMESTONES.

Many of the preceding analyses indicate small quantities of magnesia, which, when only a small percentage is present, may be used freely; but where it exceeds six per cent., it is better not to employ such limestones if others can be obtained; for although fluxing more easily than pure lime, they are considered to deteriorate the iron. The following are a few analyses of what are termed the magnesian limestone

which, for reasons already stated, ought to be avoided as a flux:—

	English.	Scotch.	Foreign.
Carbonate of lime,	54.50	53.09	55.36
Carbonate of magnesia, ..	44.93	43.49	41.30
Oxide of iron,	0.33	0.96	2.00
Silica,	0.24	2.46	0.50
Loss,	—	—	0.84
	100.00	100.00	100.00

Limestone also often contains much more silica than is shown in any of the above analyses; this is likewise a deleterious matter, as it combines with the iron and makes it very weak; consequently, limestone should all be tested previous to using it as a flux, which may be done easily. Good limestone should effervesce with great violence when put into dilute hydrochloric acid; magnesian limestone produces less effervescence. The best method of testing is to take twenty-five grains of the limestone ground and dried, and digest in a small glass flask with dilute hydrochloric acid till all effervescence ceases; the solution is then filtered, and that which remains upon the filter may be regarded as silica; this is to be dried and weighed. To the filtered solution add ammonia to neutralize the acid; this will precipitate the iron and any alumina in solution, but when these are in minute quantity the solution need not be filtered, as the presence of iron is as useful as lime. In this case, add, immediately after the ammonia, oxalate of ammonia, so long as a precipitate is formed; warm the solution, and after about thirty minutes, filter and wash; this when dried and burned at a red heat, gives the quantity of carbonate of lime. To the filtrate add a solution of phosphate of soda, which precipitates the magnesia, if any be present, as phosphate. This, after being filtered, dried, and burned, contains in every one hundred parts, 36.5 magnesia, equal to 76.7 of carbonate of magnesia—the condition in which it exists in the mineral. Thus the quality of the lime for fluxing can be easily ascertained; of course, as only twenty-five grains are used in this test, the results must be multiplied by four to get the per-centage.

Proportions of the Charge.—It has been stated that, in the assaying process, the iron is reduced from its ore by putting the mixed materials into a crucible, which is placed in the centre of the fire, so that the heat is applied to it externally. A blast furnace differs from a crucible, in so far as not only the ore and flux, but likewise the whole of the fuel, is thrown into it. For this purpose, men are constantly employed in wheeling the materials to the furnace in barrows made of sheet-iron, which are raised up by machinery to the platform round the mouth of the furnace, and their contents discharged into it, care being taken to keep the furnace full. Where the ore is a mixture of clay and black-band with coal as fuel, the charge is generally about the following proportions:—

	Hundredweights.
Calced black-band,	4.5
Calced clay-band,	4.5
Limestone,	1.5 to 2.0
Coal,	10.0

These are all mixed roughly and put into the barrows. Sometimes the very large pieces of coal are broken

into smaller ones; some smelters also break the limestone into small pieces of the size used for macadamizing roads; others think this unnecessary, from the fact that the limestone, when put into the furnace, very soon flies to pieces by the heat, and thus saves the labor of breaking by hand. Dr. URE gives the following as the practice in Staffordshire:—As soon as the furnace gets into a regular heat, the working consists simply in charging it at the opening in the throat whenever there is a sufficient empty space, the only rule being to keep the furnace sufficiently full. The coke is measured in a basket, thirteen of which go to the ton. In twenty-four hours there are thrown into a furnace, such as Fig. 280, fourteen and a half tons of coke, sixteen tons of roasted ore, and six and three-quarter tons of limestone, from which about seven tons of pig-iron are produced. But the exact proportions of the materials put into the blast furnace differ in every locality, and with every change of ore or coal.

Reactions in the Furnace.—The changes produced in the materials put into the furnace in their descent from the mouth to the hearth, where they are separated as iron and scoria, must be, to a certain extent, matter of speculation. It has been shown that the ores contain oxide of iron and silica, mixed with clay. A portion of these substances is often in a state of combination produced by the roasting operation. The lime is put in as a carbonate, which will not combine with the silica until the carbonic acid in union with the lime be driven off, and this does not take place till the limestone has descended to a considerable depth to experience the requisite heat. When lime and silica and oxide of iron are together, their combination depends upon the temperature to which they are exposed. The probability is, that the silicate of iron is the first compound formed, as it melts at a comparatively low degree of heat, and then in a melted state it trickles down, until it comes to a temperature sufficiently high to allow a simultaneous reaction of all the materials. From the results of analyses of cast-iron, it appears that a considerable portion of silicate of iron passes through the furnace without being decomposed, and mixes with the iron, rendering the metal impure. The scoria floats upon the surface of the metal, and as it accumulates, the furnace-man allows it to flow out by a hole in the side of the furnace, into large beds, where it is broken up for removal; or it is cast into large blocks and employed for building walls or any rough purpose. Every twelve hours the furnace is *tapped*; that is, the metal is let out into sand moulds of various shapes, but generally of a long semi-circular form, known technically as pigs.—See Fig. 279.

The whole process of the action of the furnace is given by TRURAN as follows:—

The changes which occur in the descending ore commence with the uncalcined ores in the throat of the furnace; they lose their moisture and volatile gases before they reach the level of the boshes, absorbing from the fuel the necessary caloric for calcination. Below this the ore is gradually converted from a sesquioxide to a magnetic oxide, or, as sometimes occurs, into metallic iron; having combined with a portion of the carbon from the fuel, to form the fusible carbide of

iron. From the bottom of the boshes to the level of the tuyeres, the reduction of the ore and flux into a liquid mass is completed. The fusion of the ore and flux occurs at a height of eight or ten inches above the tuyere, from whence it descends into the hearth. Here the metal, from its greater specific gravity, falls to the bottom, freed more or less from the fluid cinder which floats on the surface, and protects it from the oxidising influence of the blast.

Gases Evolved.—The gases passing through and escaping from the blast furnace have been the subject of several investigations by the most eminent chemists. They were obtained by inserting into the furnace the end of a wrought-iron pipe through which the gases escaped, and were conducted by a leaden tube attached to the external extremity of the iron pipe into a pneumatic apparatus, where they were subjected to analysis.

The following are the results obtained by BUNSEN of Heidelberg, the fuel used being charcoal; the proportion of the gases is given in volume:—

Height above tuyeres, Feet.	Nitrogen.	Carbonic acid.	Carbonic oxide.	Light carbide of hydrogen.	Hydrogen.
17 $\frac{1}{2}$	62.34	8.77	24.20	3.36	1.33
16 $\frac{1}{2}$	62.25	11.14	22.24	3.10	1.27
14 $\frac{1}{2}$	66.29	3.22	25.77	4.04	1.58
13 $\frac{1}{2}$	62.47	3.44	30.08	2.24	1.77
11 $\frac{1}{2}$	63.89	3.60	29.27	1.07	2.17
8 $\frac{1}{2}$	61.45	7.57	26.99	3.84	0.15
5 $\frac{1}{2}$	64.58	5.97	26.51	1.88	1.06

Subjoined are the results of a similar experiment at Alfreton by Messrs. PLAYFAIR and BUNSEN. In this table the measurement is taken from the mouth or top of the furnace downward, extending to a depth of between one and two feet above the tuyeres:—

Feet from top	Nitrogen.	Carbonic acid.	Carbonic oxide.	Carbide of hydrogen.	Hydrogen.	Olefiant gas.	Cyanogen.
5	53.35	7.77	25.97	3.75	6.73	0.43	—
8	54.77	9.42	20.24	8.23	6.49	0.85	—
11	52.57	9.41	23.16	4.57	9.33	0.95	—
14	50.95	9.10	19.32	6.64	12.42	1.57	—
17	55.49	12.43	18.77	4.31	7.62	1.38	trace.
20	60.46	10.83	19.43	4.40	4.83	—	—
23	58.28	8.19	29.97	1.64	4.92	—	trace.
24	56.75	10.08	25.19	2.33	5.65	—	trace.
34	58.05	0.00	37.43	—	3.18	—	1.34

The annexed table exhibits the relative proportion of oxygen and nitrogen at the different depths stated:

Feet.	Oxygen.	Nitrogen.
5	24.9	79.2
8	23.6	79.2
11	24.6	79.2
14	19.5	79.2
17	25.7	79.2
20	23.7	79.2
23	28.2	79.2
24	27.7	79.2
34	27.8	79.2

OVERMANN tabulates as follows the per centage of the different gases given off from a coke furnace:—

Above the tuyeres.	Nitrogen.	Carbonic acid.	Carbonic oxide.	Hydrogen.	Total.
2 ..	61.07	0.68	36.84	1.41	100.00
17 $\frac{1}{2}$..	64.66	0.57	33.39	1.38	100.00
28 ..	63.59	2.77	31.83	1.81	100.00
31 ..	60.70	11.58	25.24	2.48	100.00

The subjoined results are those obtained by Dr. SCHAFFHAUTL from the Ystalyfera anthracite furnaces:—

	Taken off one foot below the coal and ore in the furnace.	Taken off sixteen feet below the surface of the coal and ore in furnace.
Carbonic acid.....	9.546	00.136
Carbonic oxide.....	12.012	18.974
Hydrogen.....	21.278	27.834
Light carbide of hydrogen,...	2.548	3.212
Sulphurous acid, with traces of arsenide and phosphide of hydrogen,.....	0.111	trace.
Nitrogen.....	54.505	49.844
	100.000	100.000

In BUNSEN's and PLAYFAIR's elaborate report to the British Association for 1845, upon the theory
VOL. II.

of the blast furnace deduced from the examination of the gases, they conclude that the evolution of carbonic acid is owing to the reduction of the ore; and that the process of reduction takes place only in the boshes. The average proportion of the mixed gases must be somewhere between the following numbers:—

Nitrogen,.....	60.907	57.878
Carbonic acid,.....	8.370	9.823
Carbonic oxide,.....	26.846	24.042
Light carbide of hydrogen,....	2.536	2.743
Hydrogen,.....	1.126	4.972
Olefiant gas,.....	0.112	0.392
Sulphide of hydrogen,.....	0.045	0.035
Ammonia,.....	0.058	0.115
	100.000	100.000

This mixture of gases contains:—

First. The products of distillation of the coal.

Second. The products of its combustion.

Third. The carbonic acid generated during the reduction of the ore, and expelled from the limestone.

WASTE PRODUCTS.—*Cyanogen.*—Another object of inquiry into the gaseous products of the blast furnace, besides the chemical reactions going on within, was to find if there could be any application of the products, and of the great quantity of heat given out at the mouth of the furnace. It will be observed in the analyses of the gases from the Alfreton furnace by Messrs. BUNSEN and PLAYFAIR, that cyanogen was detected at the lower portion of the furnace. They found in their experiments that when they withdrew the iron tube from this part of the furnace, it was incrustated with melted cyanide of potassium, which speedily deliquesced in the air. This led to inquiry as to the source of the potassium; and by very careful analyses of the ore and coal, these were found

to contain small portions of alkali. The calcined ore gave—

Sesquioxide of iron,.....	60.242
Silica,.....	25.775
Alumina,.....	6.583
Lime,.....	3.510
Magnesia,.....	3.188
Potassa,.....	.743
Manganese,.....	traces.
	100.000

And the coal—

Carbon,.....	74.98
Hydrogen,.....	4.73
Oxygen,.....	10.01
Nitrogen,.....	0.18
Water,.....	7.49
Silicates,.....	2.61
Potassa,.....	0.07
	100.00

The presence of potassa is likewise shown in the table of the analyses of the North and North Midland ores given at page 410.

The formation of cyanogen gas by the direct combination of the nitrogen of the air with carbon at a high heat had been, previously to these experiments, pointed out by Dr. FOWNES and Mr. JAMES YOUNG. The production of cyanide of potassium in the blast furnace, and the value of it as a product, were then calculated. The mixed gases, as already seen, possessed the following composition:—

Nitrogen,.....	58.05
Carbonic oxide,.....	37.43
Hydrogen,.....	3.18
Cyanogen,.....	1.34
	100.00

Every 219.33 cubic inches of gas must contain 1192.97 grains of carbon, corresponding to 1774.79 grains of coal. Hence, out of 100 parts of coal, at least 0.778 of cyanide of potassium is generated; and as 31,200 pounds of coal are consumed every twenty-four hours in the furnace, it is obvious that at least 224.7 pounds of cyanide of potassium are generated daily in the Alfreton furnace, and hitherto have been altogether lost.

Ammonia.—Another product obtained from the furnaces is ammonia. This substance, which is present in the gases of blast furnaces fed with coal, but never found in those furnaces fed with charcoal, is often in such abundance as to be sensible to the smell in the gases collected from the deeper parts of the furnace. BUNSEN and PLAYFAIR remark that the ammonia may be obtained in the form of chloride of ammonium, if the gas, previous to its application as fuel, be conducted through a chamber containing hydrochloric acid. The advantage of its collection is, that without any further consumption of fuel, or any considerable expenditure of labor, a valuable commercial ingredient would be economized. The furnace coal of Alfreton was subjected to trials to ascertain the quantity of ammonia which might be produced by distillation, and the mean results gave 0.769 per cent.; and hence, the conclusions drawn were, that as two hundred and eighty hundredweight of coal were consumed in the

furnace every twenty-four hours, not less than two hundredweight of sal-ammoniac might be obtained as a subsidiary product, without increasing the cost of manufacture, or in the slightest degree disturbing the process of smelting.

Application of the Waste Heat.—The great value of the investigation into the gases evolved from blast furnaces, was the economizing of the fuel, and the experiments proved the combustibility of the entire column of gas, from a depth of twenty-four feet to the mouth of the furnace; hence the gas collected at any point to this depth is capable of being applied as fuel. It was found that at the Alfreton furnaces there was at least 81.54 per cent. of valuable fuel lost; and, as about fourteen tons of coal were used every twenty-four hours, it followed that 11.4 tons of coal were lost, by escaping at the mouth of the furnace in the form of gas capable of being used as excellent fuel. It was also proved, that by the combustion of these gases, a temperature could be obtained equal to what would melt iron.

After the application of the hot-blast to the furnace, several manufacturers tried to heat the air or blast by the waste heat of the furnace; adopting several methods of causing the air of the blast to pass through pipes ranged around the trunnel head, or coiled round the interior of the furnace so as to be heated by the ignited materials themselves, or built into the masonry so as to receive heat by transmission: these plans were, after various trials, abandoned. Other expedients were adopted, such as covering the top of the blast furnace, except during charging, and carrying the gases to a reservoir or gasometer, from which they were pumped into a gas furnace for heating the blast; but from several practical difficulties these plans also were abandoned.

In 1848 Mr. PALMER BUDD adopted a more successful mode of applying the waste heat of the blast furnace; part of his success lay in not making his apparatus a portion of the furnace, nor burning the gases; hence the operations did not interfere in any way with those of the blast furnace. Three or four horizontal flues, of about twelve inches diameter, are constructed about three feet below the top of the furnace, and lead into an adjoining chamber or stove provided with a stalk, which creates the draught. Into this stove he draws as much of the gaseous escape as he requires, the supply being regulated by means of a damper. The quantity required to heat the blast for a furnace, he considers to be only about one-sixth of that which passes off from the trunnel head. He does not burn the gases, but allows them to pass hot through the stove or furnace for heating the blast; they enter at a temperature of about 1800° Fahr., and leave it at a temperature of about 800°, the heat required for the blast being about 600°; and thus the mere passage of these heated gases through the stove serves his purpose.

Mr. BUDD says that his plan has several great advantages; it requires no coal or labor, the blast is better and more regularly heated, and the apparatus more durable. Besides the heating of the blast, the same ingenious manufacturer applied these heated gases to his steam-boilers, and states that the saving effected by

the application to one boiler was equal to three hundred and fifty pounds sterling per year, and the total saving in his works by doing away with the use of coal in all the boilers, fire-bars, *et cetera*, would at full worth exceed two thousand pounds sterling *per annum*.

Notwithstanding these practical results, the improvements recommended have not been generally adopted. TRURAN, while acknowledging that the gases escaping from certain blast furnaces, may, with proper management, be made to yield eighty-two per cent. of the caloric evolved during the imperfect combustion of the fuel, dissents from the generally-received opinion, that a sufficiently intense heat can be maintained by their combustion for the purposes of the forge, or for the rapid generation of steam. Although the actual heat evolved be ample for generating steam and for heating the blast, still, owing to its dissemination through such a large volume of gas, the quantity of heat in contact with the plate-iron is small, and the evaporating power is much slower than with coal fires.

At three several experiments made at the Dowlais Works, the temperature obtained rarely went above a dull red heat, and the evaporating power of the boiler, as compared with a coal fire, was reduced nearly two-thirds. At the Ebbu Vale, Aberychan, Sirhowy, Aberdare, Ystalyfera, and other establishments using the gas, the number of boilers now in use is nearly twice as many as formerly sufficed with coal fires only.

After a careful examination of the various modes of collecting the gases adopted in this country and on the Continent, and having witnessed the alterations produced on the operations of the blast furnace by each, TRURAN gives it as his opinion that it is neither expedient nor profitable to control the escape of the gases; and that where the consumption of coal is proportioned to the requirements of the case, not one particle of gas, or one unit of heat, can be withdrawn from a furnace, without disturbing the equilibrium of the smelting. This opinion is at variance with the statements of Continental chemists, but it must be remembered that their estimates of the commercial value of the products of combustion have invariably been drawn from theoretical calculations, and are based on the assumption that they may be withdrawn in quantity without affecting the smelting. But the fact of their withdrawal occasioning an alteration in the economy of the furnace, has been established in practice; and, on the whole, the brilliant anticipations formed of the value of these gases for heating purposes have not been realized. The obtaining of the iron being the primary object in all the operations of the blast furnace, whatever improvements or alterations are made must in no way interfere with either the quality or quantity of the metal produced, and every alteration affecting this must be adopted with great caution. At the same time, the practical observations above-mentioned are of the highest importance, and should stimulate to further inquiry.

STATE OF THE BLAST.—In connection with the gases evolved in the working of the blast furnace, this may be the proper place to consider the state of the blast as it is allowed to enter into the furnace. It has been seen from the analyses of the gases passing through

the furnace, that, however great the quantity of air admitted, it was all consumed, no oxygen passing through uncombined; but it has likewise been shown that it is not all profitably consumed, which is a desideratum. There is a general opinion amongst practical men, that the furnace works best and produces the largest casts, and frequently the best iron, in dry frosty weather, and the opposite when the weather is warm and moist. The irregularity of the working of the furnace from these supposed causes, led Mr. JOHN HART, a few years ago, to institute a series of experiments upon this subject. He ascribes some of the irregularities to differences in the atmospheric pressure; thus the range of the barometer in this country being about three inches, or rather more than one-tenth of the mean pressure, this change of density would produce a difference of one-tenth in the bulk of the air; and, therefore, between a severe frost with the thermometer at 20°, and sultry weather with the thermometer at 70°, the difference would be 50°; and as atmospheric air dilates or contracts one four hundred and eighty-fifth part for every degree, this difference in temperature would produce a variation of rather more than one-tenth in the mass or bulk of the air; so that, if during severe frost the barometer stood at thirty-one inches, while during sultry weather it stood at twenty-eight inches, the combined effects of the difference in temperature and pressure would amount to a total variation of one-fifth in the bulk of the blast, which would be nearly equivalent to a careless furnaceman putting into his furnace ninety pounds of coal instead of one hundred, during a whole casting. Indeed, the difference from temperature and pressure amounts to something like an irregular charging of the furnace with ninety pounds up to one hundred and twelve pounds indiscriminately, instead of one hundred pounds regularly.

There is still another source of irregularity, occasioned also by the barometric changes in the density of the air, when the power employed is the double-stroke condensing steam-engine having neither fly-wheel nor governor to regulate its speed, and whose motion is only contracted by the resistance of the blast. As the fireman keeps up his steam to the regular pressure indicated by the steam gauge, without any reference to the pressure of the air, whether it can support twenty-eight or thirty-one inches of mercury; and as the steam must always displace the atmosphere, to make room for itself: therefore the difference of pressure upon the steam-loaded piston descending into a vacuum, will be one-tenth greater when the mercury is at thirty-one than at twenty-eight inches; hence, if a blowing engine works to forty horse-power, when the barometer is at twenty-eight inches, it will work equal to a forty-four horse-power when the mercury is at thirty-one inches, and of course it will perform an additional number of strokes. However, these atmospheric changes being comparatively slow, will affect the quantity more than the quality of the iron.—*Hart*.

These observations of Mr. HART are certainly worthy of attention; the impression of the effect of moisture in the air is still as firmly held as ever. Taking the average of five years, selected at intervals

of the same period, for twenty-two years' working, the following quantities of coal were consumed for every ton of crude iron produced :—

	Winter. Cwt.	Spring. Cwt.	Summer. Cwt.	Autumn. Cwt.
Foundry iron furnace,....	49·7	52·2	53·1	55·4
Forge iron furnace,.....	43·6	44·2	44·6	45·8
Blast iron furnace,	43·2	44·1	50·1	49·5

In the first or foundry furnace, the excess of autumn over winter months is eleven per cent.; in the forge furnace equal to five per cent., and in the blast fifteen per cent.

How useful would a series of meteorological observations have been in connection with these results !

Advantages of the Hot-Blast.—The great practical discovery in connection with the blast furnace, and one which has formed an era in the iron trade, is the introduction of the *hot-blast*, which is now all but universally used by the iron smelters in this and other countries. The advantages of hot-blast are, an increased make of iron, and great economy in the consumpt of fuel. These advantages, however, are not equal in all localities, nor with all classes of ore and coals; in general, greater benefit has been experienced in Scotch than in English furnaces, either owing to the former having been working less economically than the latter, previous to the introduction of the hot-blast—thus making the saving appear greater; or else the fuel used in Scotch furnaces being in general weaker than the English, the hot-blast has consequently effected much greater comparative advantages. So early as July, 1833, a comparison of the product of the blast furnaces in the neighborhood of Glasgow, before and after the introduction of the hot-blast, gave the following results :—

By cold-blast—

	Tons.	Cwt.	Lbs.
Consumed for each ton of iron, three tons coke, equal to,	6	13	0
For the blowing engine,	1	0	7
	7	13	7

using ten and a half hundredweight of limestone.

By hot-blast—

	Tons.	Cwt.	Lbs.
Consumed for each ton of iron, raw coal,	2	0	0
For heating the air,	0	8	0
For blowing engine,	0	11	2
	2	19	2

using seven hundredweight of limestone.

The economy in fuel is proportional to the temperature of the air admitted into the furnace. This saving of fuel was accompanied by an increased make of iron of upwards of one-third, which adds materially to the advantage of using hot air.

How these effects are produced, is a question which

has not yet been answered to the general satisfaction of scientific men. The opinion of the chemist may be stated thus :—Wherever a forced stream of air is employed for combustion, the resulting temperature must evidently be impaired by the coldness of the air injected upon the fuel. There is nearly equal temperature over the whole extent of a fire-place; so that if the air and coal be very cold, the portions of heat absorbed by them might be very considerable, and sufficient to prevent the resulting temperature from rising to a proper pitch; but if they were very hot, they would absorb less caloric, and would leave more to elevate the general temperature. This excess of temperature may produce in metallurgical operations, a *play of affinities dormant at lower degrees of heat*; often a few degrees is all that is required to modify the state of a fusible body.

THE SLAGS.—Having entered at considerable length upon the gaseous products, the state of the blast, and the theory of the action, both mechanical and chemical, that takes place within the furnace, it will now be necessary to advert to the fluid or solid products; namely, the slag or scoria, and the metal. The intrinsic value of the former is nothing to the ironmaster; the great end of all the operations is the iron; but the appearance and quality of the slag is an index to the working condition of the furnace, and the quality of the iron. The furnace-manager must therefore keep a watchful eye on the state of his slags, when withdrawn from time to time. If the furnace is yielding an iron proper for casting into moulds, the slags have a uniform vitrification, and are slightly translucent. If the quantity of ore be too much in proportion to the other matters—an excess which is sometimes intentionally introduced, in order to produce a grey pig-iron fit for fabrication into bars—the slag is opaque, dull, and of a greenish-yellow tint, with blue enamelled zones. When the furnace is producing a white metal, which is an inferior quality, the slags are black, glassy, full of bubbles, and emit an odor of sulphide of hydrogen. Such are the three leading characteristics of the quality of the slags; but practice can detect the slightest tendency towards any of these conditions, so that much depends upon a careful furnace-manager.

The quality of the slag becomes, therefore, an important consideration to the smelter, as anything that will affect the obtaining of a good slag, any want of material in its composition, will affect the quality and quantity of the iron; nevertheless, the principle of good slags does not appear to depend so much on any particular composition, as on the obtaining of a slag that is perfectly fusible, and capable of taking up from the ore all the earthy matters. The appended analyses will show this :—

	I.	II.	III.	IV.	V.
Silica,	43·75	38·12	40·4	36·6	55·48
Alumina,	12·50	16·97	11·2	37·5	19·32
Lime,	31·22	32·77	38·4	20·7	14·57
Magnesia,	17·15	6·22	5·2	1·5	2·54
Protoxide of manganese and iron,	4·88	5·92	3·8	1·0	4·36
Sulphur,	—	—	—	2·7	2·43
Loss,	·50	—	1·0	—	1·30
	100·00	100·00	100·00	100·00	100·00

The first three are good slag, giving good iron; the fourth was not considered so by the workman, and led to a change in the proportion of materials, producing a white iron; the fifth is a bad slag, both in color and structure, yielding an inferior quality of iron of

the following composition:—Iron, 88·9; carbon, 3·0 silicious matters, 7·4; sulphur, ·7. The subjoined table of analyses of slags from the blast furnace, is from the report made upon that subject to the British Association by Drs. PERCY and HENRY:—

Silica,	38·05	38·76	37·63	37·91	39·52	28·32	45·59	52·31
Alumina,	14·11	14·48	12·78	13·01	15·11	24·24	11·88	5·12
Lime,	35·70	35·68	33·46	31·43	32·52	40·12	38·20	30·71
Magnesia,	7·61	6·84	6·64	7·24	3·49	2·79	—	9·50
Manganese,	·40	0·23	2·64	2·79	2·89	0·07	0·91	1·41
Protoxide of iron,	1·27	1·18	3·91	0·93	2·02	0·27	1·11	0·95
Potassa,	1·85	1·11	1·92	2·60	1·06	0·64	—	—
Sulphide of calcium, ..	·82	·98	·68	3·65	2·15	3·64	1·76	—
Loss, <i>et cetera</i> ,	·19	·74	·34	·44	1·24	0·09	0·55	—
	100·00	100·00	100·00	100·00	100·00	100·00	100·00	100·00

Phosphorus, which is a common ingredient in iron ores, and is considered to be very prejudicial to the metal produced, has been carefully sought for in the slags, and various means have been tried of causing it to combine with these in preference to the metal. Ores containing phosphorus, which may be distinguished as Nos. 1 and 2, were smelted with hot and cold blast, and the iron and slag tested for phosphorus gave the following results:—

By hot-blast the iron, No. 1, contained 0·74; No. 2, only 0·68 per cent. phosphorus, and the slag only a trace. By cold-blast the iron, No. 1, contained 0·81; No. 2, only 0·62 phosphorus, and the slag only a trace. The conclusions derived from a series of experiments were, that ordinary iron, such as the bands and hematites, whether smelted by hot or cold blast, will give the phosphorus in the iron with grey pig-iron; but if white iron is produced, and the slag contain protoxide of iron, some of the phosphorus may go away in the slag. For example, samples of slag from white iron made from pisolitic ores, gave—

Silica,	41·11	37·84
Alumina,	13·45	13·20
Lime,	29·82	20·68
Protoxide of iron,	6·44	20·83
Magnesia,	4·75	2·93
Protoxide of manganese, ..	0·66	0·80
Alkalis,	1·84	1·08
Phosphoric acid,	0·15	1·77
Sulphide of calcium,	1·34	0·87
Loss,	0·44	0·05
	100·00	100·00

This slag was considered bad by the workmen.

Various patents have been taken for the application of slags to useful purposes, especially to building. The difficulty in the annealing and in producing a com-

pound from these slags not capable of being affected by the air, combined with the cheapness of the articles for which it is to be used as a substitute, will operate greatly against the profitable and general application of such substances; still, the Editor would not wish to discourage the prosecution of any scheme for utilizing waste products of manufacture, as he considers this subject too much overlooked by manufacturers generally.

THE METAL.—The next and most important product of the blast furnace is the iron. It has been seen that this, unlike other metals, which must be pure before they can be available for useful purposes, is practically valuable in various states of impurity, or, perhaps it may be better to say, in various states of combination. Pure iron is tough, malleable, and ductile; is softened into a sort of clayey or pasty consistence by intense heat, but is not melted. In combination with carbon, it assumes various degrees of hardness, tenacity, *et cetera*, according to the quantity of that element in combination with it; but besides the carbon, there are also other impurities affecting the quality of the iron, as silica, phosphorus, manganese, and other matters found in the ore, fuel, and flux. According to the appearance it presents in fracture, it is divided into different qualities, as under:—

- No. 1.—Grey or black and soft—best quality of cast-iron.
- No. 2.—Mottled—a mixture of No. 1 with No. 3.
- No. 3.—White—an inferior iron for certain purposes.
- No. 4.—Silver iron—a still inferior quality.

From the mere analysis of cast-iron, it is very difficult, if not impossible, to discriminate the line where grey ceases and white begins, *et cetera*. The subjoined are a few of the results obtained by analyses, showing the effect of different kinds of fuel:—

IRON SMELTED WITH CHARCOAL.

The introduction and extension of the hot-blast led to a good deal of valuable investigation, both as to the chemical and mechanical qualities of the iron so produced; and the subject is yet far from being exhausted. The chemical question has been, whether that produced by the hot or by the cold blast is the purest, and what impurity prevails? The following analyses of the two products—cold and hot blast—will give a general view of the result with certain kinds of ore. The experiments were made at the Hartz:—

	Cold-blast.		Hot-blast.	
	Specific gravity, 7.43.	Specific gravity, 7.08.	Specific gravity, 7.100.	Specific gravity, 7.077.
Iron,.....	93.29	93.66	91.42	91.98
Carbon combined,..	2.78	0.48	1.44	0.95
Carbon free,.....	1.99	3.85	2.71	3.48
Phosphorus,.....	1.23	1.22	1.22	1.68
Sulphur,.....	trace	trace	trace	trace
Lime,.....	trace	—	—	—
Silica,.....	0.71	0.79	3.21	1.99
Manganese,.....	trace	trace	trace	trace
	100.00	100.00	100.00	100.00

From these analyses it appears that the hot-blast iron has more silica than the cold-blast.

The annexed analyses, however, made by Dr. THOMSON and Mr. J. TENNANT, prove that the question must be further studied in relation to many circumstances not yet taken into consideration:—

	Cold-blast. Specific gravity 6.70.	Hot-blast. Specific gravity 7.06.
Iron,.....	91.95	95.58
Manganese,.....	2.03	.83
Carbon,.....	3.85	2.09
Silica,.....	1.17	1.08
Alumina,.....	1.65	.42
Loss,.....	.15	—
	100.00	100.00

The mechanical constitution of the two products does not come so directly under the consideration of the chemist. The Editor will, therefore, merely give the results of some experiments which were laid before the British Association a few years ago. In the following table, the second column shows the force in pounds necessary to crush a cylinder, the transverse section of which is a square inch; the third column gives the force in pounds, which is required to tear asunder the same cylinder; and the ratios of these forces are shown in the fourth column:—

Description of metal.		Compressive force per square inch in pounds.	Tensile force per square inch in pounds.	Ratio
Devon iron,	No. 3—hot-blast,.....	145,435	21,907	6.638 to 1
Buffery iron,	No. 1—hot-blast,.....	86,397	13,434	6.431 to 1
“	No. 1—cold-blast,.....	93,385	17,466	5.346 to 1
Coed Talon iron,	No. 2—hot-blast,.....	82,734	16,676	4.961 to 1
“	No. 2—cold-blast,.....	81,770	18,955	4.337 to 1
Carron iron,	No. 2—hot-blast,.....	108,510	13,505	8.037 to 1
“	No. 2—cold-blast,.....	108,375	16,684	6.376 to 1
“	No. 3—hot-blast,.....	133,440	17,755	7.515 to 1
“	No. 3—cold blast,.....	115,442	14,200	8.129 to 1

From this table it appears that the resistance of cast-iron to rupture by extension varies from six to nine tons upon the square inch; while its resistance to compression varies from thirty-six to sixty-five tons. It further appears that the absolute strength of some kinds of iron, both as regards their tenacity and their power of resisting compression, is considerably increased by the hot-blast.

Owing to the very infusibility of pure iron, it would be impossible to obtain it in large quantities, were it not for what may be termed its impurities, especially

its combination with carbon. In this form it is easily fused, and, by processes afterwards to be described, the pure or malleable iron may be separated from the carbon which has served the purpose of extracting it from the ore and oxygen.

FOUNDING.—A great quantity of the iron produced by the blast furnaces is used in the state of cast-iron for a variety of purposes in the arts and manufactures. The qualities employed for this purpose are termed foundry-iron, and include the grey and mottled pig-iron, these kinds being more easily fused than the

white, which is known as forge-iron. The founder divides cast-iron into five classes:—

No. 1 is the best grey; it possesses the greatest quantity of carbon, and melts at a lower degree of heat than any of the others; it sets with a smooth surface, is soft, and has little sound when struck by the hammer.

No. 2 is lighter in the color than number one; not so soft nor so fluid when melted, nor so smooth on the surface when solidified; it is closer in the texture, and is preferable for strong parts of machinery.

No. 3 has less carbon than the other two, and is still less fluid when melted; has smaller grains, and is smoother in the fracture. This is used for very strong machinery where it is subjected to sudden and great strains, such as heavy shafts, wheels, *et cetera*.

No. 4 is not so much employed for foundry work; it is lighter in color, harder, and is sometimes employed for foundry work; it requires some experience to distinguish it from number three, and this can only be done comparatively.

No. 5, or what is termed white-iron—sometimes silver-iron—is very seldom used in the foundry; it is very brittle, and does not run into the moulds, being difficult to keep in fusion.

The distinguishing of these qualities is more dependent upon practical experience than any theoretical description of quality. The following practical directions are given by GRIER:—

When cast-iron is fractured, it exhibits a grey color, sometimes approaching to dull-white, and, in other cases, to dark-grey, with spots nearly black. The lustre is sometimes metallic, resembling freshly-cut particles of lead lying on the surface; and, in other cases, there seems to be crystals in the iron disposed in rays.

When the color is a uniform dark-grey, the iron is tough, provided there be also metallic lustre; but if there be no metallic lustre, the iron, though soft, will be more easily crumbled than in the former case. The weakest sort of soft cast-iron is where the fracture is of a dark hue, mottled, and does not shine.

The iron may be accounted hard, tenacious, and stiff, when the color of the fracture is lightish-grey with a high metallic lustre.

When the tint is light-grey, without metallic lustre, the iron is hard and brittle.

If the hue is dull-white, the iron is more hard and brittle than in the last case.

When the fracture is greyish-white, interspersed with small radiating crystals, the iron is of the extreme degree of hardness and brittleness.

The best way to try the quality of cast-iron is to strike its edge with a hammer. Should the blow make a slight impression, the iron must be in some degree malleable, and, if the specimen be uniform, it may be regarded as good for machinery; if, on the contrary, the hammer make no impression, and fragments fly off, the iron is brittle, and, consequently, bad. The soft cast-iron yields readily to the file after the outer crust has been removed, and is, in a cold state, slightly malleable.

The quality is also easily judged when in the melted state from the nature of the agitated aspect of its sur-

face. The mass of fluid seems to undergo rapid circulation within itself, inducing a constant tremor on the surface, having the appearance of ever-varying net-work; when this net-work is minutely subdivided it indicates soft iron. If, on the contrary, the iron be thrown up in large convolutions, the quality of the metal must be hard.

In founding, it is necessary to select the class of iron most suitable for the kind of articles to be cast. The furnaces used in this operation are termed cupola furnaces. These are also of various construction, and are generally urged by a blast similar to that employed for the smelting furnace, or, what is more common in foundries, by a fan-blast. Fig. 295 is a front elevation of an ordinary cupola of a large size; Fig. 296 is a vertical section in a plane at right angles to that of Fig. 295; *a* is the charging door, about two feet square, by which the pig-iron and coke are introduced

Fig. 295.

Fig. 296.

into the furnace; *b* is the tapping-hole, fifteen inches square, at which the melted metal is occasionally drawn from the furnace; *c*, *e*, not seen in Fig. 295, are the tuyere holes or orifices by which the blast enters, to afford a supply of air capable of maintaining a sufficiently intense heat in the furnace by combination with the fuel. These apertures are of considerable extent upwards, so as to admit of the tuyeres being set to any height required, which is regulated by the quantity of metal that may be collected in the furnace; for, of course, the tuyeres must always deliver their air clear of the surface of the metal. The tuyeres are knee-pipes for delivering the blast into the cupola, into which one end is directed, while the other extremity slides in an upright pipe through which the blast is con-

veyed, in the manner of a telescope-tube, so that the tuyere may be set to any height required. The under part, *d f*, of the structure below the charging door, is the most essential division, and is indeed that which gives its character to the furnace. The upper portion, *f g*, is the chimney, intended to convey away the volatile noxious products of the whole operation of fusion, being sufficiently long to pass out through the roof of the foundry. The furnace is built entirely of fire-brick, and it will be observed that the trunk is incased in cast-iron plates bolted together. The casing is in some instances cast in one or two entire cylindrical pieces, and in other instances it is made of boiler plates rivetted together. The latter is undoubtedly the more durable material, as it stands the alternate expansion and contraction with much less injury to itself. The chimney is simply bound with wrought-iron belts fastened round it at regular intervals. The whole structure stands upon a square base-plate, of which the centre is cut out into a circular aperture; this plate is bedded upon a brick or stone foundation, represented in the figures. As the bottom must be protected from the action of the melted metal which collects there, it is laid over with a bed of sand, mixed with wet loam to give it consistency. This is shown in section at *d*, Fig. 296. It is continued over the bottom and sides of the spout, *b*.

Fig. 297 represents the most approved form of fan for producing the blast. It consists of a central spindle, upon which are hung six arms, *a a*, meeting on an eye at the centre, through which the axle is passed, and by which they are fixed to the axle.

Upon each of these arms a square blade, generally of sheet-iron, is firmly fixed by rivets or bolts, and these blades constitute the propelling agents. To render them effectual, they are incased in a round box, *DD*, having a central opening, *A*, on each side

for the admission of air, and an opening, *B*, in the circumference, with a short prolongation, for the expulsion of the air. By the rapid revolution of the blades, a strong current of air sets in at the centre, and to prevent it from impinging against the cover, *D*, by which its progress would be retarded, a series of cutters, *b b*, are fixed between the cheeks around the dotted circle, which indicates the line described by the outer edges of the revolving blades. These cutters are curved, and are so placed that they may receive the air on their interior edges in the tangents to their curvatures, by which precaution the air should glide uninterruptedly upon their interior surfaces, and ought to be deflected in the direction of its motion, so as to join smoothly in with the general current which is propelled through *B*, to the tuyeres leading into the cupola.

According to experience, the iron melted in a cupola urged by a fan-blast improves more in the operation of melting than when a cylinder-blast is used, although the latter has certain advantages which the practical man considers important.

The fires in the cupola furnaces are generally kindled by putting in a quantity of wood, which is then ignited; the usual fuel, either coal or coke, is afterwards introduced, and the blast applied. When a sufficient heat is raised, and the cupola is well filled with fuel, quantities of pig-iron are thrown in, which melts in its passage down, and finds its way to the bottom or hearth in the same way as in the blast furnace. If the fuel be of good quality, having little earthy matter in it and no sulphur, the iron during this melting is considerably purified; a portion of the iron and silica in the pigs is oxidised, forming silicate of iron, which, from its less specific gravity, floats upon the surface of the metal, and is separated as scoria or slag; the remaining charge of iron is consequently much purer, and makes a stronger metal. When the fuel contains earthy matter, this combines with a portion of the iron, also forming silicate and scoria, by which means much of the metal may be lost without in any way tending to purify what remains. It is, therefore, a common custom to put into the furnace a small portion of lime, which acts as a flux upon the silica of the coal by which the iron is partially saved. Coke, which is seldom free from sulphur, is very generally used as fuel.—See analysis of coke, article FUEL.—The sulphur has a strong tendency to combine with the iron, and often to an extent sufficient to deteriorate greatly the quality of the metal in the cast, as the sulphide diffuses itself through the body of the iron. From analyses made of pig-iron before and after being fused in the cupola by certain qualities of coke, it was found to give in the former case only 0.4 per cent. of sulphur; and in the latter so much as 1.0 per cent., showing an increase of six-tenths of a per cent. derived from the fuel. The quality of the fuel for cupola furnaces should, therefore, be a primary consideration with the iron-founder. Wood charcoal, being free from sulphur, is employed with advantage where it can be had in abundance.

MANUFACTURE OF MALLEABLE IRON.—When pig-iron is to be converted into malleable or bar-iron, it has to undergo certain processes of purification, to separate the metal from the foreign matters which more or less affect its natural properties of malleability and ductility. Although these foreign matters were essential to give it the necessary fusibility for the obtaining of the cast-iron from the ore, and are, for the same reason, equally essential for the production of cast articles so valuable in machinery and other works of art, they must be got rid of in that iron which is to be used for purposes requiring the greater tenacity and strength of the pure material. The operations of refining consist in remelting and blowing upon the iron, to burn out a portion of its impurities, and then subjecting it to a process of heating and hammering, termed *puddling*, by which means, partly chemical and partly mechanical, the foreign matters are eliminated from the metal.

Refining.—The first operation, or that more generally

termed *refining*, is performed in peculiarly-constructed furnaces, called *refineries* or *running-out fires*. These are composed of a body of brick-work, about nine feet square, rising but little above the ground, and are shown in Figs. 298 and 299, the former of which is a sectional elevation and the latter a plan. The hearth, H, is placed in the middle of this, and is of a rectangular shape, being about three feet by two, and about thirty inches deep; it is formed by the junction of four cast-iron troughs, A, through which a stream of cold water is made to circulate to prevent them from being fused

Fig. 298.

by the heat. Over the hearth, and supported by iron columns, B, about six feet high, is a chimney from ten to twelve feet high, making the total height about twenty feet. The tuyeres, *f*, are placed on the longest sides of the hearth at the lip or edge, and are inclined towards the bottom so as to blow upon the bath of melted metal. The noze-pipe is incased similarly to that of the blast furnace, and water is made to circulate in the hollow space by cylindrical tubes, to prevent the tuyeres from being burned. The supply of water for this purpose is brought by the pipe, *a*, into the reservoirs, *b*,

Fig. 299.

from which it flows through the pipes, *d*, to the nozzles of the tuyeres, and thence escapes by the tubes, *e*', into the tanks, F; from these it is conveyed by the siphon-tubes, *e*, into the troughs, A. The blast arrives at the tuyeres through the mains, E, which

VOL. II.

are furnished with screw-valves at *c* for the purpose of regulating the supply. The tapping-hole, O, is placed at one of the shorter sides of the hearth, and by it the melted metal and the slag flow out into the mould, M.

The operation begins by filling the hearth or crucible portion of the furnace with coke; upon this are laid six pigs of iron from the blast furnace, and more coke is heaped upon them. The fire is kindled at bottom; after a little the blast is let on, and, as the heat increases, the iron melts and flows to the bottom; more coke is added as it burns away, to preserve the metal in a state of fusion. The iron during this operation expands, heaves up, and evolves oxide of carbon. After about two hours the metal is tapped out into pits or beds, forming large plates, upon which quantities of water are thrown with the view of rendering it brittle. The metal thus treated is very white, and possesses in general a fibrous radiated texture, consequent on its rapid cooling; it is also full of cells from the escaping of gaseous matters. In this operation there is formed a heavy black scoria, principally composed of silicate of iron with other impurities. When the iron is very inferior in quality, a small portion of lime is added to the fire to take up the earthy matters; in this case the scoria will contain lime. As already remarked, in fusing iron in the cupola the earthy matter in the coke employed requires a little lime to combine with it; otherwise, if present in any considerable quantity, it will take away much of the iron. In some places the iron is run into these refining furnaces directly from the blast furnace, a method which saves the time and fuel required to remelt the pigs; but this saving is attended with certain disadvantages which have prevented its general adoption.

The change effected upon the iron in this operation is the oxidation and consequent separation of a great portion of the impurities. The following are analyses of the results:—

	Iron from blast before refining.	Same iron after being refined.
Iron,	95.26	98.33
Carbon,	2.63	.87
Silicium,	1.38	.53
Aluminium,73	.26
Phosphorus,	trace	trace
Sulphur,	trace	trace
	100.00	99.99

The slag or scoria from the refining of the above iron gave—

Protoxide of iron,	70.3
Silica,	21.5
Alumina,	7.8
	99.6

As a general rule, the longer the blowing and consequent exposure to the oxygen of the blast, the greater the deprivation of alloys and improvement in quality; but the process may be unnecessarily prolonged.—*Truran*.

A very good criterion of the effect produced upon the iron by this process, is the composition of the cinder or slag from the operation. BERTHIER gives the fol-

lowing analyses of this slag from two different works in different localities:—

	Dudley.	Dowlais.	
Protoxide of iron,....	61.2	61.0	52.0
Silica,	27.6	36.8	42.4
Alumina,.....	4.0	1.5	3.3
Phosphoric acid,....	7.2	—	—
	100.0	99.3	97.7

The presence of the phosphoric acid in the scoria is important, as showing the use of the operation; a portion of both the silica and alumina may have been in the ashes of the fuel, so that this should be strictly attended to in these investigations. The following is an analysis of refining cinder from a work near Birmingham:—

Protoxide of iron,	61.28
Silica,	22.76
Protoxide of manganese,	3.58
Alumina,	7.30
Lime,	3.41
Magnesia,76
Sulphur,46
Loss,45
	100.00

It is very probable that several of these matters have been from the fuel. If the fuel contains much silica, the loss in iron, from this cause alone, will be considerable. In the above analysis the silica and protoxide of iron appear as one to three. The combined weight of the iron and cinder is always more than the weight of the pig-iron put in. TRURAN gives, as the result of his own experience, the following:—

	Pounds,
Crude iron put in,	2498
Produce, { Refined metal,	2240
{ Cinder,	325
	2567
Showing an excess of weight,	69

The principal portion of the excess, says this authority, is due to the fixation of oxygen forming the protoxide of iron in the cinder, silica, and alumina. The remaining portion is composed of the silicious earths of the coke and stones composing the hearth. The increase of weight by the oxygen in the scoria is counterbalanced by the direct loss of carbon; so that the increase is wholly from the last-named sources, the ash of the fuel and stones of the hearth. The loss of iron in this process varies according to the quality of the crude iron. BERTHIER gave from his results twelve to seventeen per cent. of loss; in the preceding statement of TRURAN the loss is ten per cent.

Puddling.—The next process of refining is termed *puddling*, and is performed in a reverberatory furnace of the shape shown in sectional elevation and plan in Figs. 300 and 301. The sole or hearth, D, is made of brick or cast-iron; if of the former, it is arched below, the bottom of the furnace being the top of the arch; if of the latter, it is a large plate of cast-iron, supported by pillars, and is covered with a layer of slag, which is made to incline towards E, where there is a rapid fall to allow of the escape of the slags formed during the process; these are removed at the opening or *floss-hole*, b. The length of the hearth is about

six feet; its breadth at the middle about four feet; at the chimney-end about two feet; and from two and a half to three feet at the fire-end. The fire, A, is

Fig. 300.

separated from the hearth by a wall of fire brick, a, about ten inches high, termed the bridge. The draught is produced by a chimney, F, forty or fifty feet high, and furnished at top with a damper, H, which can be raised or lowered by means of a chain and lever.

Fig. 301.

The opening, C, which communicates with the grate, is generally closed by heaping up the fuel. The opening, B, into the hearth or sole of the furnace, is that through which the workman introduces his iron bar, or *paddle*, during the process of puddling. Nearer the chimney is another aperture, G, which is used for cleaning out the furnace at the end of an operation.

From three and a half to four hundredweight of the fine metal obtained by the refining process is put into the puddling furnace, in pieces laid one upon another upon the sides of the hearth, leaving the centre or middle part free for the operations of the puddler. The furnace is then closed up, and the fire pushed to a high heat; in about twenty minutes the metal begins to melt, and falls off in drops upon the sole of the furnace. The furnaceman, by means of a paddle, removes the iron from the hottest parts to prevent its melting too rapidly. When the whole of the metal is reduced to a pasty state, the temperature of the furnace is lowered that it may not become more fluid. The furnaceman then works about the pasty metal with his paddle, during which it swells up with the discharge of gaseous matters. As this goes on, the metal becomes less fusible as it gets finer, the gases cease to escape, and by the constant puddling or kneading with the paddle, it becomes reduced to a sort of sandy consistence. During these operations, small quantities of water are thrown into the furnace. At this stage the heat is increased, and the particles of metal begin again to

agglutinate, and become, in the language of the workman, *heavy*. The furnaceman with his paddle gathers a lump of metal on the end of it, as a nucleus, and makes it roll about on the surface of the clotted mass; he thus collects a ball of about seventy pounds in weight, which is placed on the side of the hearth at the hottest part, where, with a rake or paddle, termed a *dolly*, it is squeezed as much as possible to force out any scoria. After the whole of the metal is thus formed into balls, the heat of the furnace is still augmented to facilitate the welding. The balls are then lifted out—by means of tongs, if roughing rollers are to be used, or with an iron rod, welded to the ball, if the hammer is to be employed.

The time taken to puddle a charge is from two to two and a half hours. The loss of iron in this process varies considerably, both according to its quality, and also the expertness of the workman. The loss is on an average about ten per cent. During this operation, a considerable quantity of scoria, which sweats out from the metal, is allowed to run off from the hearth, and is removed. The composition of this scoria differs little from that of the refining furnace,

except that a quantity of the iron is found in the state of sesquioxide. The following is the analysis of two samples of scoria, the one exposed in a flue of a puddling furnace for some time, and the other, called *tap cinder*, direct from the furnace:—

	Scoria found in flue.	Tap cinder.
Silica,.....	29·60	23·86
Protoxide of iron,.....	48·43	39·83
Sesquioxide of iron,.....	17·11	23·75
Protoxide of manganese,.....	1·13	6·17
Alumina,.....	1·28	·91
Lime,.....	0·47	·28
Magnesia,.....	·35	·24
Phosphoric acid,.....	1·34	6·42
Sulphide of iron,.....	1·61	·62
	101·92	180·02

These results show the impurities to be of the same kind as those of the scoria given out at the refining or running-out furnace.

The following are analyses of refined or malleable iron of different qualities, and from various localities, exhibiting the extent of the effects produced by refining, when compared with the composition of crude iron:—

	Iron.	Carbon.	Sulphur.	Phosphorus.	Silica.	Arsenic.	Copper.	Manganese.
Swedish from Danemora,.....	98·78	.. 0·84	—	.. —	.. 0·12	.. 0·02	.. 0·07	.. 0·05
Swedish common bar,.....	99·73	.. 0·24	—	.. trace.	.. 0·03	—	.. —	.. trace
German very strong rod,.....	99·13	.. 0·66	—	.. —	.. trace.	.. —	.. 0·05	.. 0·29
German strong, Hartz Mountains, ..	98·88	.. 0·40	.. trace.	.. —	.. 0·01	.. —	.. 0·32	.. 0·30
German weak, fibrous,.....	99·87	.. 0·09	.. trace.	.. —	.. 0·03	.. —	.. —	.. —
Welsh puddled iron,.....	98·90	.. 0·41	—	.. 0·40	.. 0·08	.. —	.. —	.. 0·04

In comparing these analyses with the qualities, it is difficult to say wherein lies the difference. That termed weak is the purest, and the strong Swedish iron appears the most impure.

CALVERT and JOHNSTON have recently carried out a series of researches, instituted for the purpose of ascertaining the progressive chemical changes effected in the operation of puddling.

The material operated upon was good cold-blast Staffordshire iron, No. 3, rather grey. The puddling was conducted in the usual manner; and at intervals portions of the iron were taken out from the mass, and subsequently analysed so as to ascertain the nature of the changes produced at the different stages of the operation.

The following table gives the quantity of the several portions, so far as regards the per centage amounts of carbon and silicium, which embrace what are considered the principal changes in this process:—

Pig-iron used.	Time.	Carbon.	Silicium
Iron as put in,	12 o'clock.	2·275	.. 2·720
Sample 1 ..	12·40	2·726	.. ·915
" 2 ..	1·0	2·905	.. ·197
" 3 ..	1·5	2·444	.. ·194
" 4 ..	1·20	2·305	.. ·182
" 5 ..	1·35	1·647	.. ·183
" 6 ..	1·40	1·206	.. ·163
" 7 ..	1·45	0·963	.. ·163
" 8 ..	1·50	0·772	.. ·168
Puddled bar,.....		0·296	.. ·120
Wire bar,.....		0·111	.. ·088

These interesting results show the value of such investigations; and it is to be hoped that similar experiments will be repeated again and again under various circumstances, and with a view to all the impurities.

One thing worthy of notice is the fact, that, after the furnace operations are complete, the hammering and rolling seem to eliminate a great quantity both of the carbon and silicium. The carbon in the wire-iron is only one-seventh of that in the iron at the end of the puddling operations, and the silicium is reduced nearly one-half.

With regard to the sulphur and phosphorus in the iron before and after the puddling, the final results only are given, namely:—

	Pig-iron.	Puddled bars.	Wire-iron.
Carbon,.....	2·275	.. 0·296	.. 0·111
Silicium,.....	2·720	.. 0·120	.. 0·088
Phosphorus,.....	0·645	.. 0·134	.. 0·117
Sulphur,.....	0·301	.. 0·139	.. 0·094

The following composition of the slag produced in these operations confirms the preceding results:—

Silica,.....	16·53
Protoxide of iron,.....	66·23
Sulphide of iron,.....	6·80
Phosphoric acid,.....	3·80
Protoxide of manganese,.....	4·90
Alumina,.....	1·04
Lime,.....	0·70
	100·00

Hammering, Squeezing, and Rolling.—The process of refining and toughening the iron after passing through the puddling furnaces, is completed by mechanical means; either by subjecting it to the action of large hammers, or by pressing and drawing it between rollers, during which operations a great quantity of scoriaceous matter is squeezed out, and the iron assumes a fibrous structure, possessing the malleable and

ductile qualities of wrought-iron. In the first place, the puddled balls are *shingled* or fashioned into oblong slabs or *blooms* by the blows of a heavy forge hammer, termed the *helve*. The blooms are then passed through a series of grooved iron rollers, which reduce them to the form of long bars. These are cut up into short pieces, several of which are *fagoted* together and brought to a welding heat in the *balling* furnace, after which they are again passed several times between grooved rollers, and by this latter process are made into bars or plates, ready for the shears.

The helve or shingling hammer is a ponderous beam of cast-iron, A B—Fig. 302—about ten feet long, and weighing from three to four tons. At one extremity, A, it

Fig. 302.

turns on an axis, which rests on heavy plummer blocks, and to the other is secured the *head*, B, which is of wrought-iron, faced with steel, and weighs from seven to eight hundredweight. The anvil, b, is supported on a massive block of iron, D. The head is raised by a number of cams, a a, fixed to a powerful shaft, C, which is turned by steam or water-power, assisted and regulated by a heavy fly-wheel. The ball or bloom is placed upon the anvil, and the head, being lifted from eighteen to twenty-four inches by each cam as it revolves, makes from seventy-five to one hundred blows per minute, by which the scoriæ and other impurities are separated.

Another instrument used for preparing the blooms to pass through the rollers, acts by compression like a pair of pliers, and is termed the *squeezer* or *alligator*. This machine is represented in Fig. 303. It acts by means of two powerful jaws, A B, united at C like a pair of shears, and having their faces grooved in order to hold fast the bloom, which is introduced between them. A current of water flows through a cavity in the lower jaw to keep it cool. The upper jaw alone moves, and is worked by a cam on the axis, E, of the fly-wheel, operating on the crank, D. This machine requires an attendant to keep the bloom rolling about between the jaws, A B.

The alligator is said to squeeze out the slag more thoroughly and expeditiously than the helve does; but

both are now being rapidly superseded by steam-hammers, one of the most celebrated of which is that of NASMYTH, patented in 1833. The hammering weight

Fig. 303.

in this machine is attached directly to the lower end of the steam piston-rod, and the percussive action of the blows is found to be objectionable in its effects upon the piston and rod, causing wear and serious fractures. To obviate this practical defect, Mr. JOHN CONDIE, of the Govan Iron-works, Glasgow, about the year 1846, gave the subject much consideration, and

Fig. 304.

the result of his deliberations was the hammer delineated in Fig. 304. The great difference between CONDIE's hammer and all earlier contrivances, consists in the fact that the steam cylinder is movable, and itself gives the blow, whilst the piston and its rod are fixed to the framing. The cylinder is, therefore, constructed of great strength, particularly at the lower end, which is formed with a dovetail socket, to receive the acting hammer face. This arrangement permits of the replacement of the striking portion when worn.

The first experimental Condie hammer was erected at the Govan Iron-works in 1848, and it has worked day and night since that time, doing all sorts of puddling and forging work in a most successful manner. The size of the instrument has gone on increasing in quick gradations until the climax of a six and a half tons dead hammering weight, with a fall of seven feet six inches, has been reached. All the unprecedentedly heavy shafts in the great steamer, the *Leviathan*, were forged under Mr. CONDIE's hammers at a time and under circumstances when such heavy masses could not have been shaped elsewhere. For puddling forges, hammers of forty and fifty hundredweight are now generally superseding the old-fashioned helves and squeezers.

Among the latter class of machines, however,

BROWN's patent squeezer is acknowledged to be very effective. It consists of a series of massive rollers, so arranged that the heated bloom of puddled iron, being placed on the top of the machine, is taken in between the two upper rollers, and is gradually compressed between these and others as it descends. At the bottom, it falls upon an endless revolving chain ladder, by which it is elevated and thrown on to a platform in front of the rolls for drawing it out into bars.

The drawing rolls are represented in Fig. 305, and consist of two sets, AA and BB. The former are called the *roughing* rolls, and serve to conclude the refining process by expressing the last portions of slag; the latter are termed the *finishing* rolls, and are differently grooved, according to the section intended to be

Fig. 305.

given to the bar. They are mounted in pairs, one above the other, on massive iron bearers, EE; the lower rolls are driven direct by a shaft, *d*, from the fly-wheel of the engine, and motion is communicated to the upper rolls by strong toothed wheels, CC; the distance between them is regulated by screws, *ss*, which work through the tops of the bearers. These are connected at the upper part by stout iron bars, *ff*, which serve to support the heavy tongs employed in lifting the blooms. Through the small pipes, *gg*, a stream of water is made to play upon each pair of rolls, to keep them cool, descending into a channel beneath the frame, in which the scale that falls from the surface of the heated iron, as it passes between the rolls, is carried away by the water. The roughing rolls vary from four to five feet long, and are about eighteen inches in diameter.

The bloom on arriving at the platform in front of the roughing rolls, is still at a bright heat, and is now of an oblong form. The workman immediately seizes it with a pair of tongs, and forces it into the largest groove in the rolls, the first three or four grooves being roughened with teeth, by which it is caught, and carried through without slipping. It is then passed in succession through the other grooves of the same series, until it attains the required form for railway bars or other purposes to which it is intended to be applied.

For good bar-iron, however, an additional process is required. When the blooms have been reduced by the roughing rollers to the form of long bars, they are cut into short lengths, which are welded together in piles, and again drawn out into bars in the rolling mill. A great variety of shears is used for cutting iron, some driven by cams or eccentrics, and some by con-

necting rods and a crank on the revolving shaft. In large iron-works it is necessary to have two or three kinds, some for cutting up scrap iron and bars for piling, and others for boiler-plates. The shears employed in cutting the bars for piling consist of two jaws, Fig. 306, to which are firmly bolted cutting edges, *ab*, of hardened steel. The lower blade, as in the squeezer,

Fig. 306.

is fixed, but the upper one moves on the pin, A, by the action of the bar, D, on the lever, B A. Bars of considerable thickness are easily divided by the jaws, and a number of the short lengths thus produced are placed together in *piles* or *fagots*, which are raised to a welding heat in a reverberatory furnace, taking care not to expose them to the oxidising influence of the air. The experience of the workman enables him to judge, from the appearance of the furnace, when the piles are at a welding heat, so that, when afterwards compressed in the rolls, the particles will unite. When he ascertains that this point has been attained, the piles are taken

out, one at a time, and thrown to the workmen at the finishing rolls, who pass them through the grooves as rapidly as possible, so as to elongate each pile into a bar of the required size, before the iron has cooled down below the proper temperature for drawing. The short lengths which compose the pile or fagot tend to produce a fibre in the bar, which in good iron is always perceptible, however perfect the weld, and seems to be necessary to give it strength and toughness.

Sheet-iron is made by passing the metal between smooth rollers, without grooves, the rollers being gradually screwed nearer together as the desired thickness is being approached.

The speed of the different kinds of rolling mills varies according to the work they have to perform. Those for merchant-bars make from sixty to seventy revolutions a minute, whilst those of large size for boiler-plates are reduced to twenty-eight or thirty. Others, such as the finishing and guide rollers, run at from one hundred and twenty to four hundred revolutions a minute.

BESSEMER'S PROCESS.—The nature of the changes taking place in the iron during the preceding refining operations is obvious, the whole being simply a process of oxidation of the impurities, which are subsequently squeezed out by the pressing and rolling. Since the invention of puddling by Mr. CORT, many improvements or alterations, both of a chemical and mechanical nature, have been introduced, some of which have done much to facilitate the operations; but all have been merely modifications of the same principle: the process was still essentially CORT'S. But during the year 1856, a method was patented which sets all previous plans and modifications aside, and, as with the wand of the magician, effects the refining of the iron from the crude pig to malleable bar without either fuel or hammer. Unfortunately, from various experiments tried, the practical utility of this beautiful process is still doubtful. Mr. BESSEMER, the inventor, describes it in nearly the following terms, in a paper which was read before the British Association in the year above-mentioned:—

The assumptions with which he set out were, that crude iron contains about five per cent. of carbon; that carbon cannot exist at a white heat in the presence of oxygen, without uniting therewith, and producing combustion; that such combustion would proceed with a rapidity dependent on the amount of surface of carbon exposed; and, lastly, that the temperature which the metal would acquire would be also dependent on the rapidity with which the oxygen and carbon were made to combine, and consequently that it was only necessary to bring the oxygen and carbon together in such a manner that a vast surface should be exposed to their mutual action, in order to produce a temperature hitherto unattainable in our largest furnaces. With a view of testing practically this theory, he constructed a cylindrical vessel of three feet in diameter, and five feet in height, somewhat like an ordinary cupola furnace, the interior of which was lined with fire-bricks; and at about two inches from the bottom of it, he inserted five tuyere pipes, the nozzles of which were formed of well-burnt fire-clay, the orifice of each tuyere being about three-eighths of an inch in diameter. At one side of the ves-

sel, about half-way up from the bottom, there was a hole made for running in the crude metal, and in the opposite side there was a tap-hole stopped with loam, by means of which the iron could be run out at the end of the process. In practice this converting vessel might be made of any convenient size, but he preferred that it should not hold less than one, or more than five tons of fluid iron at each charge. The vessel was placed so near to the discharge-hole of the blast-furnace as to allow the metal to flow along a gutter into it; a small blast-cylinder was employed, capable of compressing air to about eight or ten pounds to the square inch. A communication having been made between it and the tuyeres before named, the converting vessel was in a condition to commence work.

It has been stated that the tuyeres were situated nearly close to the bottom of the vessel; the molten mass would, therefore, rise some eighteen inches or two feet above them. It was, consequently, necessary, in order to prevent the metal from entering the tuyere holes, to turn on the blast before allowing the fluid crude iron to run into the vessel from the blast-furnace. This having been done, and the liquid run in, a rapid boiling up of the metal was heard going on within the vessel; the metal being tossed violently about and dashed from side to side, shaking the vessel by the force with which it moved. Flame then issued from the throat of the converting vessel, accompanied by a few bright sparks. This state of things continued for about fifteen or twenty minutes, during which time the oxygen in the atmospheric air combined with the carbon contained in the iron, producing carbonic acid gas, and at the same time evolving a powerful heat. Now, as this heat was generated in the interior of, and was diffused in innumerable fiery bubbles through, the whole fluid mass, the vessel absorbed the greater part of it; its temperature became immensely increased; and by the expiry of the fifteen or twenty minutes before named, that part of the carbon which appeared mechanically mixed and diffused through the crude iron was entirely consumed. The temperature, however, was so high, that the chemically-combined carbon now began to separate from the metal, as was at once indicated by an immense increase in the volume of flame rushing out of the throat of the vessel. The metal in the vessel now rose several inches above its natural level, and a light frothy slag made its appearance, and was thrown out in large foam-like masses. This violent eruption of cinder was generally found to last about five or six minutes, when all further appearance of it ceased, a steady and powerful flame replacing the shower of sparks and cinders which always accompanied the boil. The rapid union of carbon and oxygen which thus took place, added still further to the temperature of the metal, while the diminished quantity of carbon present allowed a part of the oxygen to combine with the iron, which underwent a combustion and was converted into an oxide. At the excessive heat which the metal had now acquired, the oxide as soon as formed underwent fusion, and formed a powerful solvent of those earthy bases which were associated with the iron. The violent ebullition which was going on mixed most intimately the scoria and metal, every part of which was thus brought in contact with the fluid

oxide, which thus washed and cleansed the metal most thoroughly from the silica and other earthy bases combined with the crude iron; while the sulphur and other volatile matters which cling so tenaciously to iron at ordinary temperatures were driven off, the sulphur combining with the oxygen and forming sulphurous acid. The loss in weight of crude iron during its conversion into an ingot of malleable iron, was found on a mean of four experiments to be twelve and a half per cent., to which would have to be added the loss of metal in the finishing rolls. This would make the entire deficiency probably not less than eighteen per cent., instead of about twenty-eight per cent., which is the loss on the present system. A large portion of this metal was, however, recoverable, by treating with carbonaceous gases the rich oxides thrown out of the furnace during the boil. These slags were found to contain innumerable small grains of metallic iron, which were mechanically held in suspension in the slags, and might be easily recovered.

It has been stated, that after the boil had taken place, a steady and powerful flame succeeded, which continued without any change for about ten minutes, when it rapidly fell off. As soon as this diminution of flame is apparent, the workman will know that the process is completed, and that the crude iron has been converted into pure malleable iron, which he will form into ingots of any suitable size and shape by simply opening the tap-hole of the converting vessel and allowing the fluid malleable iron to flow into the iron ingot moulds placed there to receive it. The masses of iron thus formed, are found to be perfectly free from any admixture of cinder, oxide, or other extraneous matters, and are far more pure, and in a forwarder state of manufacture, than a pile formed of ordinary puddle bars. And thus it will be seen, says Mr. BESSEMER, that by a single process, requiring no manipulation or particular skill, and with only one workman, from three to five tons of crude iron pass into the condition of several piles of malleable iron in from thirty to thirty-five minutes, with the expenditure of about one-third part the blast now used in a finery furnace with an equal charge of iron, and with the consumption of no other fuel than is contained in the crude iron.

To those who are best acquainted with the nature of fluid iron, it may be a matter of surprise that a blast of cold air forced into melted crude iron is capable of raising its temperature to such a degree as to retain it in a perfect state of fluidity after it has lost all its carbon, and is in the condition of malleable iron, which, in the highest heat of our forges, only becomes a pasty mass. But such was the excessive temperature which Mr. BESSEMER was enabled to arrive at with a properly-shaped converting vessel and a judicious distribution of the blast, that the fluidity of the metal was not only retained, but so much surplus heat created, as to remelt the crop ends, ingot runners, and other scrap that was made throughout the process, and thus to bring them without labor or fuel into ingots of a quality equal to the rest of the charge of new metal.

The ingots of malleable metal so formed, were found to have no hard or steely parts, such as exist in puddling iron, requiring a great amount of rolling to blend

them with the general mass; nor do such ingots require an excess of rolling to expel cinder from the interior of the mass, since none can exist in the ingot, which is pure and perfectly homogeneous throughout, and hence requires only as much rolling as is necessary for the development of fibre.

One of the most important facts connected with Mr. BESSEMER'S system was stated to be, that all the iron so produced was of that quality known as charcoal iron: not that any charcoal is used in its manufacture, but because the whole of the processes following the smelting of it are conducted entirely without contact with or the use of any mineral fuel; the iron resulting therefrom being, in consequence, perfectly free from those injurious properties which that description of fuel never fails to impart to iron that is brought under its influence. At the same time, this system of manufacturing malleable iron was considered as offering extraordinary facility for making large shafts, cranks, and other heavy masses; since any weight of metal that can be founded in ordinary cast-iron by the means at present in common use, could thus be founded in molten malleable iron, and be wrought into the forms and shapes required, by simply increasing the size and power of the machinery to the extent necessary to deal with such large masses of metal.

So far as the principle of Mr. BESSEMER'S process is concerned, it is certainly a beautiful application of chemical knowledge to practical purposes; but in its present probationary state it would be premature to venture more than a congratulation to the inventor upon the correctness of his inductions, although many of the most ingenious theories have been found inapplicable, from some cause involved in the very nature of the operation. What could have been more beautiful than DAVY'S application of zinc protectors to the copper sheathing of ships, or what more completely successful in accomplishing the object intended; and yet its perfect success was the cause of its being unsuitable. One evident defect in the practical result of the process, is its failure to free the iron from phosphorus and sulphur, which is certainly a serious drawback, as shown by the following analysis of iron refined by this method:—

Iron,.....	98.90
Carbon,.....	0.05
Sulphur,.....	0.16
Phosphorus,.....	1.08
	<hr/> 100.19

From the analyses of wrought-iron which have been given, it will be seen that its comparative weakness or strength has no apparent relation to its chemical purity; a circumstance suggesting the probability that there may also be mechanical requirements in preparing malleable iron, which the puddling process supplies. Mostly all metals, when melted and left to solidify undisturbed, do so in a crystalline form. The stirring and working in the puddling operations may prevent this crystallization in the metal, and hence the tenacious and fibrous character of wrought-iron. Time and experience are required to prove the practicability of the best inventions, and these often enable the experimenter to modify the pro-

cesses, so as to overcome the collateral difficulties that arise in the first applications. Should such difficulties exist in the present case, Mr. BESSEMER will have the sympathy of all men of science, and their best wishes for the success of a process at once beautiful, ingenious, and simple. It may be remarked here that perfectly pure iron seems not to be desirable; it is very malleable and ductile, and might do for wire, but its softness would be a considerable objection for many requirements. The iron wanted must be hard as well as tough, and this is the object to be aimed at.

LOSS IN REFINING.—On looking back upon the refining operation, the quality of the crude iron from the blast furnace, and the state of the malleable iron produced, there is one circumstance which must strike every reader with surprise; namely, the great loss of metal which takes place in the refining. Something is evidently wanting in the process to reduce this deficiency. Mr. BESSEMER gives the loss in the common process at twenty-eight per cent.; of course this will vary according to the quality of the cast-iron used, but in many localities the loss has been found to average nearer thirty-three than twenty-eight per cent. The proportion of loss will be more apparent when stated thus:—If pig-iron having six per cent. of silica be refined with coke containing three or four per cent. of the same substance, and if, as shown by the analysis of the cinder, every part of silica represents three of protoxide of iron, consequently the gross loss cannot be much less than one-third of the pig-iron, especially when one takes into consideration the other sources of silica with which the iron may be brought into contact in the process of refining both in the running-out and puddling furnaces. Even in the mere operation of remelting to produce cast-iron articles for machinery, the loss from the formation of cinder is very considerable.

The cinder, however, although lost to the manufacturer of malleable iron, is not entirely thrown away; in many places it is collected and re-smelted with lime flux, by which an inferior iron is obtained. It is also often mixed in small quantities with the ordinary ores in the blast furnace; but their presence generally affects the quality of the iron produced. A patent was recently taken by Mr. CALVERT to recover the iron from rich cinders; but no good and effective method has yet been applied.

SWEDISH IRON.—Notwithstanding the facilities enjoyed in this country, and the great improvements in the manufacture of iron, still the qualities produced on different parts of the Continent are preferred—particularly those of Sweden, Norway, and Russia—and command a higher price in the English market than the British best iron; but the ores from which the iron of these countries is made are much richer, the quantity of iron produced is less, and the fuel is of a superior kind, namely, charcoal.

At the smelting works of Sweden and Norway, the principal ores from which the iron is manufactured are the magnetic oxide, the composition of which has been already given. According to M. JARS, the smelting furnaces of Sweden and Norway are about thirty feet high from the tuyere-hole to the base

of the chimney. The time required by the ore to descend from the top of the furnace to the tuyere is very considerable, during which time it is mixed up with charcoal under the effects of a constant and regularly increasing heat; and the ore, having little or no earthy matters in it, the iron is gradually reduced to the metallic state by loss of its oxygen, and then by an increased heat it combines with from three to six per cent. of carbon, in which state it is more easily kept in a fused condition. This fused metal runs down into the hearth, and is from time to time let out, as in the process of smelting in this country. It is then introduced into a refining furnace, which consists of a low quadrangular stack of masonry, with a sloping ledge inside, just opposite the tuyere-hole, and on this the crude-iron is placed and covered with charcoal, to prevent the iron from burning away by the action of the blast, which is directed so as to strike upon the under surface of the pig, and the latter is pushed forward from time to time in proportion as the lower part is melted away by the blast. When all is fused, a man with an iron bar keeps stirring and intermixing, while the blast is continued. In a short time jets of flame arise from the surface of the metal, and soon after it becomes of a thicker consistence; it is then gradually solidified, and is removed from the furnace to the hammer. How close is this in principle to BESSEMER's new process?

The scoriæ stirred into the melted metal, says BERZELIUS, consist of oxide of iron vitrified with silica and other earthy substances, all of which contain oxygen, and this, reacting on the carbon of the cast-iron, separates it in the state of inflammable gas—carbonic oxide. The best quality of Swedish bar-iron was found by the above-mentioned illustrious chemist to contain half a per cent. of carbon and one-tenth of a per cent. of silicium.

As already stated, much of the superior quality of the iron produced in these countries depends more upon the purity of the ore and the fuel, than on any difference in the mode of manufacture. When coke or mineral coal is used by the same method, and for the same ores, the iron produced is very inferior; and when the ordinary ore of this country is treated by the same process, even with charcoal, the iron produced is not equal to that made from the best ore and charcoal, showing how much depends upon the character and quality of the fuel.

The most celebrated iron mine of Sweden is that of Dannemora, about thirty miles to the North of Upsala. It is imported into England, chiefly at Hull, and is known as *Oregrund* iron, from the name of the port at

Fig. 307.

which it is shipped. Foreign iron is generally imported in bars, on which certain marks are stamped by the manufacturers. The marks which distinguish the Swedish iron are shown in Fig. 307. The different qualities of the *Oregrund* are known as the *hoop L*—so called from being marked with the letter L enclosed

in a circle or hoop—the *G L*, and the *double bullet*. Inferior Swedish iron is known by the marks *C* and *crown*, *D* and *crown*, the *steinbuck*, and the *W* and *crowns*.

STEEL.—Steel is a compound of iron and carbon, nearly in the proportion of five equivalents of carbon and seventy-three equivalents of iron, giving the formula $\text{Fe}_{73} \text{C}_5$, and is manufactured from the purest malleable or bar iron, such as the charcoal iron of Sweden and Russia. It is generally divided into four qualities—namely, Damascus steel, German steel, blister steel, and cast-steel.

Damascus steel derives its name from the city of Damascus in Asia, which, from the earliest time, has been famed for producing a steel of remarkably superior quality, and eminently fitted for swords or scimitars—hence Damascus *blades* have long been proverbial. The surface of these blades presents a variegated appearance of *watering* in white and black lines. A similar effect has been given to other steel; but the quality of the metal has never been surpassed in this country. It is of the nature of cast-steel, and is a little more highly charged with carbon than European steel, but the characteristic quality of metal is obtained by some peculiar mode of cooling and conducting the operations.

M. BREANT, who devoted much time to the production of this kind of steel, made some excellent blades by mixing one hundred parts of soft iron with two parts of lamp-black, and fusing. This was considered an easy method of making cast-steel without the previous cementation of the iron. A good Damascus steel was also obtained by mixing one hundred parts of the best grey cast-iron with an equal amount of the same iron reduced to filings and oxidised, and then fusing the two together. This gave a metal remarkable for its elasticity. In making this steel, care should be taken to stir the materials during their fusion, before they are allowed to set. The iron filings should be as fully oxidised as possible before being used; for when the carbon is in excess, the steel produced is difficult to forge, except within a very narrow range of heat, and the proper temperature has to be carefully watched.

Indian steel is found very difficult to work in this country, in consequence of our workmen not studying the particular temperature at which alone the steel will forge easily. Experience, says URE, has taught that the orbicular veins which are seen upon the finest Eastern scimitars are the result of the manner of forging them, as well as the method of twisting the Damascus bars. If these be drawn in length, the veins will be longitudinal; if they be spread equal in all directions, the stuff will have a cylindrical aspect; if they be made wavy in the two directions, undulated veins will be produced like those in the Oriental Damascus.

The mode of manufacturing steel in the East, at the present day, is probably the same as was practised in the earliest age in which there is any reference in history to the use of that article. The iron is made from the magnetic oxide by the means which were formerly adopted in the old bloomeries. When about to be converted it is made into small pieces, and packed in

crucibles formed of clay. From one to two pounds of iron is put into each crucible with about one-tenth of its weight of chopped wood, and is then covered with clay to exclude the air. When the crucibles and covers are dry and well tempered, about twenty-four of these are built in the form of an arch within a small furnace; the whole are then covered over with charcoal, the mass is ignited, and the fire is kept up by a blast during from two to three hours, when it is allowed to go down, and the crucibles are removed. When cold, they are broken, and the steel is obtained in the form of a cake at the bottom. This product is known as Indian steel, or wootz, and is said to be superior to the best English steel for the purposes of fine cutlery.

BLISTERED STEEL, OR STEEL OF CEMENTATION, is largely manufactured in Great Britain, particularly in Sheffield. The furnace in which the operation is conducted is represented in Fig. 308. *c* is the grate and hearth; *AA* are chests or troughs made of the best

Fig. 308.

fire-clay; *aa* are flues leading to the chimney to assist the draught; and at the back is a door by which the men enter for the purpose of filling and emptying the troughs. The whole is built under a large cone or chimney, from forty to fifty feet high, resembling the dome of a glass-house.

The troughs are of various dimensions, according to the size of the furnace and the taste of the manufacturer, varying from eight to sixteen feet in length, and from two to three feet in width, and the depth generally corresponding to the width. Small troughs are considered to produce the most uniform quality of steel. They are so set in the furnace, that a space is left under and round the sides, to allow the flame of the fire to play all round them. The troughs are charged by laying first in the bottom a layer of about two inches of fine charcoal-powder, mixed up with one-tenth of ashes and common salt, which is technically called the *cement*. Upon this are placed the bars of iron, separated from each other about half an inch; and upon these is laid, to the thickness of one inch, more of the charcoal-powder, and then another layer of bars; and so on in successive strata, till the trough is filled to within a few inches of the mouth; the remaining space is filled up with old cement-powder, and there is then put upon the whole as a covering a layer of damp sand, or fire tiles.

The furnace is now fired, and heated carefully till the

temperature of the trough reaches about 100° Wedgwood, which should take from three to four days. This temperature must be steadily maintained until pieces of the metal, taken out by *proof-holes* at the ends of the troughs, show the process of conversion into steel to be complete, which requires, according to circumstances, from four to eight days. A few of the bars are allowed to project for this purpose. When the furnace is cooled, the troughs are opened and the steel-bars removed; they are found to be covered with blisters, and hence the term *blistered steel*. This steel is irregular in its texture, and has more or less of a crystalline appearance in proportion to the carbon absorbed. It is then subjected to the operation of tilting under powerful hammers, by which it is made more uniform, and fit for any useful process in tool-making. Good blistered steel should be of a greyish color, and possess a bright lustre, and should exhibit a coarse grain of a lamellar structure. That which is of a white color and fine-grained is inferior.

In the process of conversion much depends upon the degree of heat, and the regularity at which the heat is maintained, for producing a good article. No small experience is required for properly conducting these operations; and even with the most careful workmen, the charge occasionally proves bad. When the iron is good, it augments in weight during its conversion into steel; but bad iron increases very little. The best iron for making blistered steel is that from Sweden, although some English charcoal iron has occasionally produced very good steel.

SHEAR-STEEL.—Shear-steel is made from blistered steel; and is so called from the circumstance of the shears used for dressing woollen cloth being made from it, although it forms also the material of many other important manufacturing tools. It is prepared by binding together with a slender steel rod several short lengths of blistered steel, one of which is left longer than the rest, or a pole of iron is used for a handle, as shown in Fig. 309. The *fagot* is then put into the hearth of the forge, and brought to a welding

Fig. 309.

heat, a little sand being sprinkled over the bars, to produce a skin of scoria or glass over the surface, so as to protect them as much as possible from the air. The *fagot*, when removed from the furnace, is placed under a forge-hammer, which unites all the fragments, and closes up the internal fissures and cavities that always exist in blistered steel. A solid mass or bar is thus produced, which is again heated, the binding rings are knocked off, and the tilt-hammer, Fig. 310, comes into operation. This machine is similar in principle to the shingling hammer already described; but in shingling, where only a slow motion is required, the hammer is lifted up by means of levers attached to a cam revolving under the nose of the helve, whereas in the tilt-hammer the cogs of a wheel, *b*, are made to act upon the tail, *d*, of the helve, pressing it down, and thus causing an elevation of the head of the hammer

with a greater rapidity of motion, on account of the comparatively small arc described by the tail. The helve of the tilt-hammer is made of timber secured by

Fig. 310.

wrought-iron rings, and the head, which is also of iron, falls from two to four hundred times per minute upon the mass of steel, *b*, which is placed on the solid anvil, *a*. The workman is seated on a board suspended by iron rods from the ceiling of the mill-house, whereby he is enabled, with a slight motion of his foot, to advance or recede, and holding in his hand the pole, *o*, Fig. 309, to cause every part of the welded pile to receive the blows of the hammer in quick succession. By this operation, the steel is formed into bars of about an inch and a half broad, and three-eighths of an inch thick; all the seams and fissures of the blistered steel are closed, and it is now capable of being forged with the hammer into shears, edge-tools, and cutting instruments, or drawn out by rollers according to the use for which the metal is to be applied.

During these operations, even when great care is taken, the steel loses a portion of its carbon; and much attention is required to prevent its being reconverted into common iron. Shear-steel is more compact, malleable, and ductile than blistered steel, and much more easily wrought into shape.

CAST-STEEL is much harder, and much less malleable and ductile than shear or blistered steel, but may be wrought at a certain temperature; and, consequently, great care is required to notice the particular degree of heat required for the working of it. It is made by taking the most highly carbonised blistered steel, breaking it into convenient pieces, packing them into a crucible along with a little slag or broken glass to protect from oxidation, and fusing in a wind furnace. The crucibles for this purpose are made of very refractory clay, mixed with a small quantity of coke dust, and kneaded with the naked feet during five or six hours. This is put into a cylindrical mould of cast-iron, *a*, Fig. 311, which is open at both ends, and is inserted into a sole, *b*, also of cast-iron. In the centre of the sole, corresponding with the axis of the cylinder, is a hole to receive the supporting-rod of the inner mould, *c*, which consists of a block of hard wood. Through the centre of this block passes a strong iron axis, the upper part of which is rounded into a knob, *d*. The

surface of *c*, and the inner surface of *a*, having been smeared with oil, a quantity of clay is put into *a*, and the block, *c*, is then forced down by blows of a hammer, until the lower end of the axis, *d*, enters the hole in the sole, *b*. The black portion around *c*, shows a section of the crucible thus formed. To disengage it from the mould, the interior block or core is pulled out by means of the handle, *d*, and the hole made in the bottom of the clay by the lower end of the axis is filled up. The mould, *a*, is then separated from the sole, *b*,

Fig. 311.

Fig. 312.

Fig. 313.

and the disc of wood which is seen on the tip of the iron rod, *t*, Fig. 312, is placed for a support under the exposed bottom of the crucible, to which it exactly fits. The exterior mould is then allowed to descend slowly, by which means the clay pot is left upon the top of the block of wood, as shown in the same figure. It is finished by hand, the top being pressed slightly inwards, and made to assume the form represented in Fig. 313. The crucibles are about two feet in height,

and weigh about twenty-five pounds. They are placed in short cylinders of clay, *e*, and the covers are thick discs, *f*, of the same material, slightly raised in the centre. Each crucible is removed as soon as it is finished into a heated vault, where it gradually becomes dry, and some hours before being used the crucibles are brought to a red heat, for the purpose of annealing them.

The furnace employed for melting the steel is simply a square prismatic cavity, of about fourteen inches on each side, and a depth of two feet. Iron bars are placed to support the fire. In most establishments several of these furnaces are so arranged along the walls, that the mouth is but a little above the floor of the foundry, for the convenience of the men lifting out and putting in the crucibles. The furnaces are also all connected to a chimney, so as to have a strong draught, and obtain a high temperature. The crucible, with its charge of steel, is inserted into the cavity or fireplace, then packed all round and over with coke, and a cover put on the mouth; and in a short time a powerful heat is raised, by which the steel, in the course of from three to four hours, is melted. The crucible is then removed from the fire, the cover taken off, and the steel poured into cast-iron moulds.

Cast-steel is much used for cutting and other edge-tools, being very hard. If a piece of polished iron be placed in the mould when the steel is cast, the iron and steel adhere, and may be rolled together. By this means many edge-tools are made, such as plane-irons, in which the part forming the edge alone is steel; so that not only a much cheaper article is produced, but one having the toughness of ordinary iron, while the cutting part has the hardness of the steel.

Another method of making steel, is by the conversion of cast-iron into what is termed *natural steel*. Much of this quality is prepared in Germany, where the best cast-iron is produced. As the presence of silica and earths in steel is very hurtful, it will be evident that only the purest cast-iron can be employed. The best for this purpose is that made from spathose iron ores, containing a small portion of manganese. The iron to be converted is cast into plates; a charcoal fire is kindled in a hearth, similar to that used for the refining of iron, and the iron plates are melted before the blast; to the fused mass is added a quantity of iron scale and rich scoria, which are considered to assist in the oxidising of the carbon in the iron.

The workman carefully watches the progress of the operation. After a small portion of the iron is melted, it is allowed to stand until, by the oxidising of its carbon, it becomes solidified into a pasty consistence; a little more cast-iron is melted into this, which renders the mass again fluid; after a time, the whole assumes once more its former state, and this operation is repeated, and continues until from three hundred to four hundred pounds of metal are added; care being taken to allow the melting iron to drop into the hearth in the centre of the charge, by which the mass acquires the appearance of a series of rings, the centre portion being fluid, and the rings becoming more and more pasty or spongy towards the circumference. After the scoria is let off, the whole mass of iron is removed from the hearth and cut into pieces in lines radiating from the centre to the circumference; these pieces are drawn into bars, but from the nature of the whole operation, different qualities of steel will exist in the same bar. To remedy this defect, the bars are made red-hot, and plunged into cold water, after which the refiner raises each bar by one end, and brings it down with a slight force upon an anvil placed upon the floor, by which means the most brittle parts of the steel break off, and are collected; after which the remaining portion of the bar is again brought down with a much harder stroke, which detaches other portions of the bar, and thus the different qualities are separated.

The parts broken off are examined, and, according to certain appearances of the fracture, are subjected to other manipulations, to give them density, which is done by welding together pieces of different qualities; the mass is afterwards tested in the same way by the refiner first heating it and plunging it into cold water, and then proceeding as before, repeating these operations till a perfect uniformity is obtained. The whole process must be watched carefully, as the metal gradually loses carbon, and would soon be reduced to common iron; to prevent this, the metal is covered during heating with a mixture of clay and oxide of iron, which forms a slag on its surface protecting it from the blast. These operations produce steel of very excellent quality, but it is at a considerable cost, both of time and material.

In those countries where German steel is made, a remarkable article is manufactured which deserves notice; it is harder than the best steel, and so brittle that it cannot bear any bending when cold. This article is cast-iron. It is derived from the remelted

steel-metal. From two hundred to two hundred and fifty pounds of this metal are melted down in the bottom of the forge hearth; a small portion of it is let off; it should be tapped as low at the bottom as possible. This mass, which flows like cast-iron or cast-steel, is broken into small pieces, and pounded into a flat piece of wrought-iron, which has a brim drawn up around it. This piece serves as a crucible. It is covered with loam, and exposed to a heat which will melt the cast-iron, and unite it firmly with the wrought-iron. The former then forms a thin coating of steel over the one side of the iron, of immense hardness. This does not become soft even though a long time is consumed in tempering it. Wrought-iron plates furnished with such a coating of steel, are used as draw-plates for wire. The holes for the wire are punched when it is warm, for, when cold, its hardness is so extreme that no drill-bit can make any impression on it.—*Overman.*

New Processes for Making Steel.—As may be supposed, a manufacture of such importance as steel could not fail to be the subject of many experimental trials and improvements, both in the processes of cementation and casting; and several patents have been taken out for new processes and modifications of the old. Some of these have been successful, and are included in the operations already described; while others have not been sufficiently economical or advantageous to warrant a change from existing plans. A curious and interesting process, considered in its chemical reactions, was suggested several years ago by Mr. MACINTOSH. His apparatus consisted of a furnace constructed in the form of a double cylinder, one surrounding the other, and containing the fire between them; the iron bars, to be converted into steel, were suspended in the internal cylinder; and, when they were at a red heat, there was passed through the interior cylinder a current of common coal-gas which the iron decomposed, combining with the carbon and becoming steel.

So great is the affinity between iron and carbon at a high heat, that at first sight the chemist is surprised to find the process not much more perfect than it really is; for experience teaches that there are many defects in the present modes of manufacture, from causes that have not yet been fully investigated, but which produce great irregularities in the quality and economy of the article. It may be that this same strong affinity between the constituents of steel, and the consequent ease with which the carbon will combine with the iron in different proportions, so as to produce different qualities of compound, may be the origin of the evils felt; and that to produce good steel the carbon and iron must be combined in a certain proportion. To take cast-iron having five per cent. of carbon in it, and at great expense and labor convert this, first into malleable iron by taking away the carbon, and then into steel by giving it back the carbon with equal labor and cost, seems a circuitous operation. If the difference between cast-iron and steel merely consist in the circumstance that the former contains more carbon than the latter, it would appear more consistent to deprive the cast-iron of just so much carbon as would

leave exactly the required proportion for making steel. Hence some such process as BESSEMER'S would seem the true course.

Upon this principle is based a patent of F. UCHARTINS, the specification of which sets forth the object of the invention to be, to reduce the cost of manufacturing cast steel by economizing the labor of the process. To this end, the inventor takes pig-iron of the purest quality, and melts it in a suitable furnace, and while in a molten state he runs the metal into cold water, and thereby reduces it into granulated iron. It is now in a suitable condition to undergo the process which will convert it into cast-steel. This mode is founded on the well-known fact, that cast-iron enwrapped or surrounded by any oxygenized materials, and subjected to a cementing heat for a given time, will yield up a portion of its carbon, which will combine with the oxygen driven off from the surrounding materials, and form carbonic oxide or carbonic acid gas. If this process is interrupted before completion, a partially decarbonized iron will result, the surface of which will have been converted into a pure iron, while the interior parts remain unchanged; or, in other words, the progress of the decarbonizing action will depend on the amount of metallic surface brought into contact with the oxygen-yielding material with which the iron is surrounded. In order, therefore, to expedite this operation, the pig-iron is reduced, as before mentioned, to a granulated state; and further to economize fuel and labor, the heat required for effecting the decarbonization of the iron is employed to reduce the metal, when sufficiently decarbonized, to a molten state; and thus by one and the same heating it is converted into cast-steel, which only needs to be forged to prepare it for the market. The granulated iron is mixed with about twenty per cent. of roasted pulverized sparry iron ore and four per cent. of fire-clay, and then placed in fire-clay crucibles, and subjected to heat in a cast-steel blast-furnace of an ordinary construction. By thus subjecting the granules of iron in presence of the sparry iron ore to a melting heat, the enwrapping oxides will first effect a partial decarbonization of the granulated iron, which decarbonization will be limited in amount according to the size of the granules operated upon; and by reason of the continued application of heat, the iron will melt and separate, with the assistance of the melting residues of sparry iron ore, from the impurities with which it was mixed, and also bring down with it a portion of the iron contained in the sparry iron ore, thereby increasing the yield of cast-steel by about six per cent.

The quality of the steel is capable of being by this process considerably modified. Thus the finer the pig-iron is granulated, the softer will be the steel made therefrom. The softer sorts of welding cast-steel may be obtained by an addition of good wrought-iron in small pieces, and the harder qualities by adding charcoal in various proportions to the before-mentioned mixture.

CASE-HARDENING.—Thin films of steel are formed upon the surface of iron articles, such as keys, gunlocks, tools, *et cetera*, by a process technically termed case-hardening. The article to be case-hardened is finished, or nearly so, in iron, and then heated to a bright red. When in this state, it is sprinkled or

rubbed over with powdered yellow prussiate of potassa—ferrocyanide of potassium. The salt is decomposed by the heat and iron, and the surface combines with the carbon of the salt, forming steel; or the operation may be performed by making a strong solution of ferrocyanide of potassium in water, then adding clay to make a thin paste. The iron article to be hardened is coated over with this paste, and dried slowly at a fire; it is then submitted to a white heat, and afterwards plunged into water when the heat has become reduced to a visible red.

TEMPERING.—One characteristic quality of steel is its being susceptible of having its hardness much increased by heating it strongly, and plunging it while hot into cold water. Different qualities of steel are affected in different degrees by this process of *tempering*. To know the degree of heat which is best fitted for any particular quality of steel, requires much experience. The practical test is to draw a bar into a tapered point, such as a chisel, and temper it; the thin tapered part will be variously affected in the process by the different rates of heat and cooling; by breaking off pieces from the point inwards the character of the grain will show the difference of temperature which has been applied; the finest and closest grain being considered the best. Such steel, then, is tempered with due relation to the test heat. The degree of hardness depends, in a great measure, upon the heat of the steel, and the coldness of the medium in which it is cooled. To give different effects different mediums are used, such as saline solutions instead of water. Mercury and oil are also employed. By this tempering process, steel may be made of any degree of hardness. The common method is to heat the steel and harden it in water, and then to anneal it, by reheating to a particular temperature, such, for instance, as that at which tallow or oil will burn when put on it; or the steel, being ground and polished, is then reheated, until it assumes a certain color, which indicates a certain degree of hardness. The gradations of the hues are a light straw, violet, blue, slate, and finally black. With this last color, the steel has become as soft as if it never had been hardened.

Several explanations have been offered of the changes in constitution through which the steel passes in the operations of tempering; but none of them are very satisfactory. It seems to be probable, says URE, that the ultimate molecules are thrown by the sudden cooling into a constrained state, so that their poles are not allowed to take the position of strongest attraction and greatest proximity, and hence the mass becomes hard, brittle, and somewhat less dense. The more sudden the cooling of ignited steel, the more unnatural and constrained will be the distribution of its particles, and also the more refractory, an effect produced by plunging it into cold mercury. This excess of hardness is removed in any required degree by judicious annealing or tempering. The state of the carbon present in the steel may also be modified by the rate of refrigeration, as, Mr. KARSTEN and M. BREANT conceive, happens with cast-iron and the damask metal. If the uniform distribution and combination of the carbon through the mass determine the peculiarity of white cast-iron, which

is a hard and brittle substance; and if its transition to the dark-grey and softer cast-metal be effected by a partial formation of plumbago during slow cooling,—why may not something similar be supposed to occur with steel, an analogous compound?

Alloys of Steel.—A few years ago, a series of experiments were made both in this country and on the Continent, to combine steel with other metals, for the production of an alloy or superior quality of steel. These experiments tended to show that steel, combined with very small quantities of platinum, silver, rhodium, or iridium, was much increased in hardness; but no extensive practical application ensued.

Composition of Different Kinds of Steel.—The whole operations in the manufacture of iron and steel, and their relation to each other, form a subject of great interest, and one which requires a thorough investigation—not confined to isolated experiments, but embracing both practical skill and chemical knowledge. One thing apparently essential to the production of good steel, is pure iron; but still, when the various qualities of steel have been analysed, there appears something which suggests further inquiry. The following are a few of these analyses:—

The first was a steel manufactured from iron produced from an ore of carbonate of that metal and manganese; it is termed Brescia steel, and is celebrated for hardness and elasticity. It is made in Styria, and is much used for cutlery; and gave—

	Centesimally.
Iron,.....	98.06
Carbon,.....	1.94
Sulphur,.....	trace
Silica,.....	trace
Copper,.....	trace
	100.00

The second was made from common Swedish iron, smelted from magnetic iron ore, which often contains silica, titanium, and copper; it was converted into steel in England, and is termed common English cast-steel. It was composed of—

Iron,.....	97.00
Carbon,.....	1.72
Silica,.....	0.22
Arsenic,.....	0.07
Copper,.....	0.07
Manganese,.....	0.02
	100.00

The third was made from Dannemora iron, smelted from magnetic iron ores. The steel was made in Sheffield, and is called best razor steel. It is uniform and hard, very fusible, and will not bear much heat. It gave—

Iron,.....	93.80
Carbon,.....	1.43
Sulphur,.....	1.00
Silica,.....	0.52
Arsenic,.....	0.93
Antimony,.....	0.12
Nitrogen,.....	0.18
Manganese,.....	1.92
Loss,.....	0.10
	100.00

The iron in the fourth was obtained from spathose iron ore, containing lime, copper, sulphur, silica, and

manganese. The steel was very tough, and known as Solingen or Siegen steel. It is admirably suited for swords. It gave—

Iron,.....	97.88
Carbon,.....	1.70
Sulphur,.....	trace
Silica,.....	0.04
Copper,.....	0.38
Tin,.....	trace
	100.00

The fifth and sixth were, like the first, made from Styrian iron which had been smelted from a carbonate of iron and manganese. Fifth is a very hard and brittle steel, and will not take a fine edge. The sixth is an inferior steel. They gave—

	5.	6.
Iron,.....	98.87	98.44
Carbon,.....	1.13	0.97
Sulphur,.....	trace	trace
Silica,.....	trace	0.50
Loss,.....	—	.09
	100.00	100.00

In comparing the composition of some of the malleable irons with No. 6, it would be difficult to say in what the difference consists, so far as the chemical composition is concerned. In wootz, or Indian steel, aluminium is found. As these different qualities of steel have each peculiar properties, rendering one more suitable for certain purposes than another, the question may be asked—Do these different properties depend upon the different impurities?

Mr. C. BINKS, in a series of interesting experiments upon the manufacture and true composition of steel, has advanced suggestions of very great importance. His experiments were conducted upon iron, submitted to different reagents, at a full red heat, as in case-hardening, or in the cementation-process. His results were as follow:—

1. That a small rod of iron packed in boxwood charcoal in a closed porcelain tube, and kept at a full red heat for twelve hours, did not, after being tempered, show a hard steel surface, nor did it exhibit, under high and different degrees of heat, the play of colors peculiar to real steel. It still remained malleable iron;

2. But when atmospheric air is admitted to such an arrangement, in such quantity only as still to keep the carbon in excess, then, in the first instance, the surface of the iron, and, finally, if the time of contact be long enough, the whole of the iron is converted into steel.

3. That the application to the iron of nitrogen gas does not produce steel.

4. That neither does the application of carbonic oxide give steel.

5. That the application to the iron of a hydrocarbon—as when olefiant gas is passed through the tube, or when the red-hot rod is dipped into oil containing no nitrogen—does not produce steel;

6. But that the application of olefiant mixed with ammoniacal gas, or the application of gaseous cyanogen, produces steel, as does also the dipping of the hot metal into a nitrogenised oil or fat.

7. That the application of ferrocyanide of potassium, as has been so long known, gives steel.

8. That equally with the ferrocyanide does the application of simple cyanide of potassium result in the production of steel; therefore, it is not to the iron contained in the ferrocyanide that the steel-making property of the latter salt is due.

9. That potassa applied to the hot iron, or the keeping the hot iron in the vapor of potassium, does not yield steel.

10. That with iron of the kind that has so far been referred to and used, *id est*, commercially pure wrought iron, containing no material proportion of carbon, the application to it of ammoniacal gas, or of nitrate of ammonia, fails to produce steel;

11. But that the application of ammoniacal gas or chloride of ammonium to iron containing a considerable proportion of carbon, ninety-five to five, results in its conversion into steel.

These results tabulated, and the composition of the reagents expressed in chemical formula, will better exhibit the inevitable deductions to which they lead:—

1. $\text{Fe} + \text{C}$ —in excess, every other element excluded,.....} leaves iron.
2. $\text{Fe} + \text{C}$ —in excess + atmospheric air,.....} gives steel.
3. $\text{Fe} + \text{N}$ —nitrogen,.....} leaves iron.
4. $\text{Fe} + \text{C O}$ —carbonic oxide,.....} leaves iron.
5. $\text{Fe} + \text{H}_4 \text{C}_4$ —olefiant gas,.....} leaves iron.
6. $\text{Fe} + \text{H}_4 \text{C}_4$ —in excess + NH_3 —ammoniacal gas,.....} gives steel.
7. $\text{Fe} + \text{N C}_2$ —cyanogen,.....} gives steel.
8. $\text{Fe} + \text{K}_2 \text{Fe Cy}_3$ —ferrocyanide of potassium,.....} gives steel.
9. $\text{Fe} + \text{K Cy}$ —cyanide of potassium,.....} gives steel.
10. $\text{Fe} + \text{KO}$ —potassa,.....} leaves iron.
11. $\text{Fe} + \text{K}$ —potassium,.....} leaves iron.
12. $\text{Fe} + \text{NH}_3$ —ammoniacal gas,.....} leaves iron.
13. $\text{Fe} + \text{N H}_4 \text{Cl}$ —chloride of ammonium,.....} leaves iron.
14. $\frac{\text{Fe} + \text{C}}{95 \quad 5} + \text{N H}_3$ —ammoniacal gas,.....} gives steel.
15. $\frac{\text{Fe} + \text{C}}{95 \quad 5} + \text{N H}_4 \text{Cl}$ —chloride of ammonium,.....} gives steel.

The conclusions drawn from these experiments are thus stated by the author:—

That the substances, by the application of which to pure iron it is converted into steel, all contain nitrogen and carbon, or nitrogen has access to the iron during the operation.

That carbon alone added or applied to pure iron does not convert it into steel.

That nitrogen alone so added or applied does not produce steel; but that it is essential that both nitrogen and carbon should be present, and that no case can be adduced of conversion in which both of these elements are not present and in contact with the iron.

That both nitrogen and carbon exist substantially in steel after its conversion; and the presence of both is the real cause of the distinctive physical properties of steel and of iron, in which latter these elements do not exist.

That presumptively, but not demonstratively, the form of combination is not that of cyanogen—though that compound plays so important a part in conversion—but is that of a triple alloy of iron, carbon, and nitrogen.

Lastly, that experimental research is yet required to determine the relative proportions of the elements when their union gives pure steel.

The reader will perceive that these investigations and their results are deeply interesting, and throw an entirely new light on the composition of steel. May not

the nitrogen take the place of that portion of carbon which is eliminated from the cast-iron during the process of its conversion?

Passive State of Iron.—The curious property which iron exhibits of passing into what has been termed the *passive state*, may not be entirely without its effects upon the different conditions and combinations of this metal. It shows, at all events, that its molecules are easily thrown into a peculiar condition in relation to other bodies; as, for instance, if a piece of iron is put into nitric acid of specific gravity 1·3 to 1·35, it dissolves freely with effervescence; but if a piece of platinum wire be placed in the acid, and then the iron be introduced in contact with the platinum, the acid will not now act upon the iron, even if the platinum is withdrawn. Another piece of iron put into the acid in contact with the previous piece, will become affected in the same way; and so on with a third or with more pieces, so that this simple contact effects some important change in the molecular state of the metal. A great many other methods are known of making iron passive—by oxidising one extremity in the flame of a lamp; by making it the positive pole of a battery; by a blow; by previous immersion in concentrated nitric acid, *et cetera*. This peculiar condition can be easily annulled by rubbing the piece of passive iron, or bringing it into contact with active iron. These phenomena are not yet satisfactorily explained, and ought not to be overlooked in any investigation into the properties of iron, even with reference to its chemical applications.

ALLOYS OF IRON.—Cast-iron and steel, which are compounds of iron and carbon, with perhaps nitrogen, do not properly fall under the designation of alloys, which are compounds of two or more metals.

Iron combines, however, with several other metals, and forms alloys, some of which are interesting to the chemical inquirer; but few of them have much practical value.

With potassium iron forms an alloy, which is white, malleable, and so soft as to take impressions from the nails of the hand, oxidising easily in the air.

With the metals of the earths iron combines, and produces hard, white, and brittle alloys of no known value; but it appears capable of taking up only a small quantity of these metals.

Iron combines with titanium, which is often found with it in the products of the blast furnace; but it seems incapable of taking up any great quantity of that metal; for, although the two metals are fused together, they readily separate, and only a small portion of the titanium remains with the iron.

Iron and molybdenum form an alloy of a bluish-grey color, hard, brittle, fine-grained, and magnetic. When formed of equal parts of the two metals, this alloy is fusible before the blowpipe; but if formed of two parts of molybdenum and one part of iron, it is not so. The following curious and interesting analyses of pig-iron, containing molybdenum in quantity along with other metals, are taken from GMELIN'S *Handbook of Chemistry*:—

I. Pig-iron from the upper works at Eisleben, obtained in the fusion of bituminous marl-slate in smelting furnaces; fine-grained.

II. Ditto; coarse-grained.

III. The so-called Magdeburg meteoric iron, containing slag mixed with bronze, yellow copper cinder, probably the pig-iron from a copper furnace; fine-grained sample.

IV. Ditto; coarse-grained sample.

V. The same substance, analysed by WEHRLE.

VI. Pig of iron found in the neighborhood of the *Rothehütte* in the Hartz.

VII. Pig of iron found underground at Sauchstadt.

Iron and manganese combine together, forming an alloy whiter and more brittle than iron; and when the proportion of manganese is about twenty-two per cent., the alloy ceases to have magnetic properties.—*Mushet*.

Arsenic and iron combine and form alloys of a white color, hard and brittle. When fifty-four parts of iron filings and one hundred and eight parts of arsenic are ignited together in a close vessel, they combine into an alloy which does not fuse, but is easily pulverised,

and is composed of two equivalents of iron and one equivalent of arsenic.—*Gehlen*.

Iron and antimony, when heated together, fuse into a mass with combustion. When one equivalent of antimony and three of iron combine, they form a hard, brittle alloy, slightly magnetic, and having a density below the mean given by calculation. The alloy of one part of iron and two parts of antimony gives sparks when filed.

Iron and bismuth form a very brittle alloy. It is attracted by the magnet when the iron is only one-fourth of the bismuth.

Iron and zinc combine with difficulty, producing alloys that are very brittle.

Iron and lead do not readily combine. When slag containing lead and iron were reduced together, a brittle alloy was formed of a steel-grey color, and magnetic, composed in one hundred parts of—

Iron,.....	96.76
Lead,.....	13.24
	100.00

Iron and tin combine together in various proportions. Twenty-two parts tin and one part of iron give an alloy much harder than tin, and magnetic. Two parts iron and one part tin give a white, hard, and slightly malleable alloy, and difficult to fuse. In recovering the mercury used in silvering glass, an alloy of tin and iron is obtained, having the following properties:—Specific gravity, 8.733; brittle, and fuses at a white heat; when in powder, and put into the flame of a candle, it burns with emission of sparks and a white smoke; and does not rust when moistened with water and exposed to the air; it is composed of—

Iron,.....	57.86	57.9
Tin,.....	42.14	42.1
	100.00	100.00

being equivalent to $\text{Fe}_3 \text{Sn}$.

Nickel and iron combine and form a very hard alloy, which is that found in meteoric stones. Cobalt, copper, silver, gold, platinum, palladium, and other more rare metals, all combine in small proportions with iron, producing alloys of no known value in the arts.

STATISTICS.—The following table from a paper by Mr. KENYON BLACKWELL, on the Iron Industry of Great Britain, which was read before the Society of Arts a few years ago, gives the estimated production of crude iron in the principal countries of Europe at that period:—

	Tons.
Great Britain,.....	3,000,000
France,.....	750,000
United States,.....	750,000
Prussia,.....	300,000
Austria,.....	250,000
Belgium,.....	200,000
Russia,.....	200,000
Sweden,.....	150,000
Various German States,.....	100,000
Other countries,.....	300,000
	6,000,000

It will be seen, therefore, that Great Britain produces as much crude iron as all the other countries put together. The subjoined statement, extracted from the Mining Records, published under the direction of Mr. R. HUNT, in connection with the Museum of Practical Geology in London, gives the state of the manufacture in Great Britain in 1854:—

Counties.	Number of works	Number of furnaces erected.	Number of furnaces in blast.	Total produce in tons.
ENGLAND:—				
Northumberland, Durham, and Yorkshire,.....	37	106	80	348,444
Derbyshire,.....	13	33	25	127,500
Lancashire and Cumberland,.....	2	5	3	20,000
Staffordshire,.....	72	203	166	847,600
Shropshire,.....	13	34	28	124,800
Gloucestershire,.....	4	7	5	21,990
WALES:—				
Flintshire, Denbighshire,.....	7	11	9	32,900
Glamorganshire—anthracite district,.....	14	35	21	750,000
Glamorganshire and Monmouthshire—bituminous dis- trict,.....	34	134	100	
SCOTLAND:—				
Ayrshire,.....	9	41	30	249,600
Lanarkshire,.....	13	88	72	468,000
Other counties,.....	10	27	16	79,040
	228	724	555	3,069,874

The importance which Scotland has assumed in reference to the iron manufacture, as shown in the preceding table, is well worthy of notice. This appears still more strikingly in the following statement given by TRURAN for 1855:—

District.	Number of furnaces.	Mean weekly produce of each furnace.	Annual production of crude iron in tons.
South Wales,.....	169	118	1,042,776
Do., anthracite,.....	37	72	139,880
Dean Forest, North Wales, and Lancashire,.....	33	67	115,460
South Staffordshire,.....	169	108	948,520
North Staffordshire,.....	19	104	102,960
Derbyshire,.....	30	101	158,080
Shropshire,.....	34	86	151,720
Yorkshire,.....	31	72	116,480
Northumberland,.....	79	132	541,320
Scotland,.....	145	145	1,082,640
Total,.....	746	113	4,399,836

Sheffield and its neighborhood is the great seat of the steel manufacture. The annual quantity of steel produced during the last five years, says TOMLINSON, varies from sixteen thousand to seventeen thousand tons from foreign iron, and from one thousand five hundred to two thousand tons from iron of British manufacture. The number of converting furnaces is upwards of one hundred and twenty, each of which is capable of converting weekly six tons of iron; the coal consumed in the process is about equal to the weight of steel produced.

The cost of converting cast into malleable iron averages about three pounds per ton. Mr. TRURAN states that the conversion of Scotch pig-iron into bars is largely pushed in Wales; and that the bars so manufactured, after paying freight from and to Glasgow, undersell the produce of local manufactories of bar or malleable iron.

About three-tenths of the quantity of iron produced, says MACCULLOCH, is used in the state of pig or cast-iron, and is consumed principally in Great Britain and Ireland. The exports of pig-iron, however, amounted in 1850 to about one hundred and forty-two thousand tons, sent principally to the United States, Holland, Prussia, France, and British North America. The other seven-tenths are converted into wrought-iron, being formed into bars, bolts, rods, *et cetera*. The exports of bar-iron amounted in 1850 to nearly four hundred and forty-three thousand tons; and, during the same year, the exports of all sorts of iron reached the prodigious amount of seven hundred and eighty-three thousand four hundred and twenty-three tons, which, at seven pounds a ton, would be worth five million four hundred and eighty-three thousand nine hundred pounds sterling. And their declared value did in fact amount, in 1850, to five million three hundred and fifty thousand and fifty-six pounds sterling.

SALTS OF IRON.—It has been shown that iron is susceptible of two definite degrees of oxidation, forming a protoxide— Fe O —and a sesquioxide— $\text{Fe}_2 \text{O}_3$. Both these oxides are salifiable, giving rise to ferrous and ferric salts. The most important is the native *protocarbonate*, which constitutes the principal source of British iron, and has, therefore, been fully described in treating of the ores of this metal.

Protonitrate— Fe O, NO_3 —is formed when very dilute nitric acid is digested upon iron filings; but is a very unstable compound, and passes into *pernitrate* by exposure to the air. The latter is a deep-red liquid, occasionally used in dyeing.

Protochloride— Fe Cl —results from transmitting dry hydrochloric acid gas over iron at a red heat, when hydrogen gas is evolved, and the surface of the iron is covered with a white crystalline protochloride. Also, by acting with hydrochloric acid on iron, evaporating to dryness, and heating to redness in a tube without exposure to the air. It dissolves freely in water, yielding a pale-green solution, from which rhomboidal prisms of the same color are obtained by evaporation. The aqueous solution absorbs oxygen from the air, and becomes yellow from the formation of sesquichloride.

Sesquichloride— $\text{Fe}_2 \text{Cl}_3$ —is formed by the combustion of iron wire in dry chlorine gas, or by transmitting that gas over iron moderately heated, when it is obtained in small iridescent plates of a red color, which deliquesce readily, and dissolve in water, alcohol, and ether. The readiest mode of obtaining it in solution, is to dissolve sesquioxide of iron in hydrochloric acid.

But the only salts of iron of great commercial importance are the *protosulphate* or *green vitriol*, and the double haloid salt, the *ferrocyanide* of iron, better known as *prussian blue*. To these the Editor will, therefore, confine his attention in what follows; but, in connection with the latter, it will be necessary to describe the preparation of another important salt, in which iron occurs as an element, the *sesquiferrocyanide of potassium*, known commercially as *prussiate of potassa*.

PROTOSULPHATE OF IRON.—Syn. Green Vitriol, Copperas; *Couperose verte*, French; *Eisenvitriol*, VOL. II.

Schwefelsaures Eisenoxydul, German.—This salt, which has many important applications, is usually formed for medicinal and chemical purposes by dissolving iron filings or turnings in dilute sulphuric acid, filtering and evaporating the solution, and setting it aside to crystallize. The crystals are sea-green, transparent, rhomboidal prisms, and have a strong styptic inky taste. Exposed to dry air, they effloresce; in moist air, the salt gradually absorbs oxygen, and is partly converted into a sesquisulphate, becoming of a rusty or reddish color, whence the French term *couperose*, corrupted into the English name *copperas*. BONSDORFF has shown, that when perfectly pure it does not change vegetal blues, though generally stated to do so, the reddening effect being only produced when some of the iron of the protoxide passes into a higher state of oxidation. It is soluble in two parts of cold, and in three-fourths of its weight of boiling water. Crystallized protosulphate of iron contains seven equivalents of water, and is, therefore, represented by the following formula, $\text{FeO, SO}_3 + 7 \text{HO}$. When heated, it fuses in its water of crystallization, and at 238° loses five equivalents of water, but retains one equivalent till heated above 535° . At a red heat, it evolves anhydrous sulphuric acid, and by this process sulphuric acid used formerly to be prepared; hence it was termed *oil of vitriol*. The residue, consisting of *peroxide* of iron, which remained in the vessel, was known under the name of *Caput mortuum vitrioli*, or *colcothar*. The fuming sulphuric acid is still prepared from the protosulphate in this manner.

The copperas of commerce is usually prepared from the pyritous schists of the coal measures, in connection with the manufacture of alum. By referring to the article on that subject—Vol. I., pp. 155–7—it will be seen that iron pyrites, or the bisulphide of iron— Fe S_2 —is present in very large proportion in many aluminous schists, and that it is quite as indispensable to the production of alum as the alumina itself. When the schists are subjected to calcination in heaps, the sulphur of the bisulphide of iron absorbs oxygen from the air, by which it is converted into sulphuric acid, and this combines with the other ingredients, forming a sulphate of alumina and protosulphate of iron. These salts are extracted by lixiviation in the same waters; and therefore the next operation is to separate the iron salt from the aluminous, when both have been obtained in solution in the same vat. For this purpose the solution is evaporated in large cisterns, by carrying the flue of a furnace over its surface, and when sufficiently concentrated is run into coolers, where the sulphate of iron crystallizes, and the sulphate of alumina, being the much more soluble salt, remains in the mother-liquors. The process of separating the two salts by crystallization varies, however, in different manufactories, according to the quantity of sulphate of iron present; and the various methods adopted, with the nature of the changes that occur, will be found fully explained in the article already referred to.—See Vol. I., page 162.

The commercial article, prepared as above-described, is by no means pure; but generally contains a small proportion of alum, of the sesquisulphate, and other

ingredients, some of which increase its value for particular purposes. In dyeing black, for example, that copperas is preferred which contains sesquisulphate, and is known by its darker green color. The excess of acid in some kinds of copperas is objected to; and those in which the crystals are small do not fetch so high a price as when the crystals are large. The following table, from PAYEN, indicates the composition of specimens from different French manufactories:—

	Paris.	Honfleur.	Noyon.	Forges.
Water,	47.5	48.7	48.40	46.60
Acid in excess,	3.4	1.5	—	—
Sulphate of {	47.9	49.5	46.80	48.00
	0.8	0.2	1.11	1.90
	0.3	0.1	0.19	0.95
	—	—	0.99	0.35
	0.1	—	—	—
Alum,	—	—	2.51	2.20
	100.0	100.0	100.00	100.00

It will be observed from the preceding table that the copperas prepared at Paris and Honfleur is absolutely free from copper and alum, and is, therefore, of very great purity. This arises from the fact that in those localities it is prepared by the direct process, instead of obtaining it from the pyritous shales in connection with the manufacture of alum.

The original materials employed are iron turnings and shavings, obtained from establishments where such operations are conducted, and sulphuric acid of 18° or 23° Twaddell, which is also a residue obtained from the rectification of certain lamp-oils. The acid is poured into rectangular copper vessels, strengthened by iron plates, and heated by means of a fire below, the flames of which play under and around the sides of the vessels. The iron turnings, previously sifted, are then introduced, agitating from time to time with wooden stirrers, and adding more turnings in proportion as they dissolve in the liquid. The oxidised portion of the iron dissolves directly; the more abundant metallic portion becomes oxidised by seizing on the oxygen of the water, and causing the disengagement of its hydrogen, mixed with different volatile products arising from the rectification of the oils and other organic matters. These gases and vapors are given off with the steam, and the liquid is maintained for eighteen to twenty hours in a state of constant ebullition, by which it is gradually more and more concentrated. The strong and offensive odor exhaled during this operation would greatly inconvenience the neighborhood, were not the precaution taken to cover the boiler with a hood, from which the gases and vapors are conveyed through a wide tube into a tall chimney creating a powerful draught.

When the concentration has reached its proper limit, which is known by observing the crystallization when some drops of the solution are put upon a plate of porcelain or earthenware, the liquid is drawn out with a pump constructed of copper, and flows by a gutter into a cellar, where it is left for a period of eighteen to twenty-four hours, to deposit the matters in suspension. The clear solution is then transferred by means of a siphon into sluices, by which it is conducted into other vats, measuring about seven feet in diameter, by three or four in depth.

These are the crystallizing vats. Planks are laid

across them, pierced with holes, through which slips of wood are suspended vertically in the solution. The crystals which form on the sticks, and on the sides of the vat, are transparent, and exhibit the ordinary green color. At the end of eight or ten days, if the temperature of the air be not too high, the crystallization is finished; and the mother-water is made to flow out, to be conveyed back to the boiler along with the sulphuric acid and iron turnings. The sticks are taken out, and the crystals at the bottom, mixed with the deposited sediment of impurities, are taken to be redissolved. The crystals adhering to the sticks, and to the sides of the vat, are detached and rapidly dried, to avoid the formation of a rust-colored salt, which would tarnish the crystals. They are then put into barrels for the market.

Copperas is extensively used in dyeing black, especially for hats; in making ink and prussian blue; for reducing indigo in the blue vat; in calico-printing; and in many chemical and medicinal preparations. Its value as an ingredient in dyeing black, and in making ink, arises from the special reaction of the iron with the tannin contained in nut-galls, oak-bark, catechu, and different tinctorial substances. It promotes the solution of the indigo by a deoxidation of the coloring principle. On these applications, see the articles DYEING and INK. Copperas is used also for the decomposition of chloride of sodium in the fabrication of soda, and in making the *protoacetate of iron*, for which see Vol. I., page 41.

Sesquisulphate of Iron.—This salt— $\text{Fe}_2 \text{O}_3, 3 \text{SO}_3$ —is formed by mixing with a solution of the protosulphate exactly half as much sulphuric acid as that salt contains, and adding to the mixture in a boiling state successive portions of nitric acid until nitrous fumes cease to appear. The solution is then evaporated to dryness to expel the excess of nitric acid, and the sesquisulphate remains as a white salt. It is formed in the mother-waters of the protosulphate, and, according to DUMAS, the two salts are capable of crystallizing together and forming a kind of double salt. It is this combination which imparts to much of the protosulphate of commerce a dingy grass-green color, whereas the pure sulphate of the protoxide furnishes hydrated crystals which are of a bright bluish-green.

FERROCYANIDE OF IRON.—Syn. PRUSSIAN BLUE; *Bleu de Prusse*, French; *Berliner blau*, German.—This celebrated pigment was accidentally discovered by DIESBACH, a color-maker at Berlin, in 1710, from which it became generally known as Prussian or Berlin blue. The first description of the mode of preparing it was given by WOODWARD in the Philosophical Transactions for 1724. It is a compound of iron and cyanogen, and, therefore, its true composition was unknown till the latter body was discovered by GAY-LUSSAC in 1815.

At common temperatures and pressures, cyanogen is a colorless gas, and has a penetrating and peculiar smell, somewhat resembling that of bitter almonds. It was so named by its discoverer, from two Greek words—*kuanos*, blue, and *gemmao*, to produce—because it is essential to the formation of *prussian blue*.

It is composed of two equivalents of carbon and one of nitrogen; its formula is, therefore, C_2N ; its symbol is Cy, and its equivalent 26. It unites as a compound radical with oxygen, hydrogen, and most other non-metallic elements, and also with the metals. United to one equivalent of hydrogen, it forms *hydrocyanic* or *prussic acid*, which is, therefore, expressed by the formula $H\text{Cy}$, or NC_2H . In combination with iron, cyanogen forms a variety of double compounds, the composition of which is best explained by assuming the existence of a radical which contains one equivalent of iron in combination with carbon and nitrogen in the same proportion as they exist in cyanogen, but in such quantity as would form three equivalents of the latter, and which radical, by uniting with two equivalents of hydrogen, forms a bibasic acid. This hypothetical radical— $Fe + 3\text{Cy}$ —is termed *ferrocyanogen*, and its symbol is Cfy ; the acid— $Cfy + H_2$ —is termed hydroferrocyanic acid; and the compounds of the radical with the metals are distinguished by the same adjuncts to ferrocyanide as are used for the corresponding oxides.

Prussian blue is regarded as a compound of three equivalents of ferrocyanogen with two of iron, and its composition is therefore expressed by the formula $3\text{Cfy} + 2\text{Fe}$, or $Fe_2\text{Cy}_6$. It is formed whenever a salt of sesquioxide of iron is added to a soluble metallic ferrocyanide. The usual method is to precipitate a solution of sesquichloride or sesquinitrate of iron by ferrocyanide of potassium; and in point of fact a very important part of its manufacture consists in the preparation of this latter salt, which will now be described.

Ferrocyanide of Potassium, better known as *prussiate of potassa*, may be viewed as a double cyanide of iron and potassium, $Fe\text{Cy} + 2\text{K Cy}$. It is prepared on a large scale by fusing substances which are rich in nitrogen, as horn, hoof, and dried blood, with carbonate of potassa, in *iron* vessels. The result of the fusion, at a red heat, is a dark-grey mass, which, when lixiviated with boiling water, yields a solution which the Germans call *blutlauge*, or *blood-lic*, and when this has been sufficiently concentrated, it affords, on cooling, crystals of *yellow prussiate of potassa*, which are composed as follows:—

	Centesimally.
1 Eq. cyanide of potassium,.....	61.80
1 Eq. cyanide of iron,.....	25.47
3 Eqs. water,.....	12.73
	100.00

The crystals are transparent, of a lemon-yellow color, and are found in large quadrangular plates or short prisms, with truncated edges and angles, which belong to the square prismatic system. They dissolve in four parts of cold, and in two of boiling water. They are permanent in the air at common temperatures, but at 212° lose their water of crystallization, without changing their form, and acquire a whitish color.

Ferriidcyanide of Potassium or *Red prussiate of potassa*, is formed by passing a current of chlorine through a solution of the yellow prussiate, until a portion of the liquor, taken for trial, is found to give no precipitate with a salt of sesquioxide of iron. The solution is

then filtered and evaporated *in vacuo* by means of sulphuric acid, when small acicular crystals of a garnet-red hue are obtained; and on purifying by successive crystallizations, the *red prussiate* is obtained in large transparent crystals, combining with a ruby-red tinge an almost metallic lustre. These crystals are anhydrous, and are composed of—

	Centesimally.
3 Eqs. cyanide of potassium,.....	59.20
1 Eq. sesquicyanide of iron,.....	40.80
	100.00

This salt—the formula of which is $K_3\text{Cy}_6\text{Fe}_2$ —is formed by the abstraction of one equivalent of potassium from two equivalents of the yellow salt. The red salt is used in calico-printing, and both are employed in *de laine* printing, as well as in dyeing wool; the blue from the red prussiate being found more durable when fixed by binocide of tin.

In most metallic solutions the two prussiates occasion precipitates of a characteristic color, which renders them of great importance in analytical chemistry, especially in qualitative analyses. In these reactions, the metal in solution takes the place of the potassium, and the resulting products are a soluble salt of potassa, and a double cyanide of iron and of the metal in solution, which, being usually insoluble, is precipitated.

With *protoxide of iron*, the red prussiate gives a dark-blue precipitate; the yellow prussiate, a white precipitate, which almost immediately becomes blue when exposed to the air.

With *sesquioxide of iron*, the red prussiate gives no precipitate; the yellow prussiate, a dark-blue precipitate, which is *prussian blue*—

	Centesimally.
3 Eqs. cyanide of iron,.....	46.00
2 Eqs. sesquicyanide of iron,.....	54.00
	100.00

In the process which is usually followed for the fabrication of prussian blue, the product obtained has always a variable composition; because, instead of employing pure sesquioxide of iron, use is made of the sulphate of the protoxide or *green vitriol*, which is only partially converted into sesquisulphate, and still retains a greater or less proportion of protosulphate. This last gives, with the yellow prussiate, a white precipitate, which, as above stated, becomes blue by absorbing oxygen from the air, and forms a basic salt, which is distinguished from the true prussian blue by its solubility in pure water, giving it a fine blue color. This basic salt must not be confounded with another blue which is obtained by pouring slowly the sesquinitrate of iron into a solution of prussiate of potassa, keeping the latter constantly agitated. In this case the precipitate produced is partly soluble in pure water, which it colors a fine dark-blue. On evaporating the menstruum to dryness a brilliant residue is obtained, which has the appearance of a varnish, is almost completely soluble in water, and consists of a combination of neutral prussian blue with the yellow prussiate of potassa.

The insoluble prussian blue is found in lumps more

or less compact, with a dull fracture, of a dark-blue color presenting a reddish reflexion, but assuming, when rubbed, a fine metallic bronze lustre, and altogether much resembling indigo. It is completely soluble in water and alcohol, and is not affected by dilute acids. Concentrated sulphuric acid converts it, in the cold, into a whitish pasty mass, which, when diluted with water, becomes decomposed, and gives a precipitate of prussian blue. Heated with concentrated sulphuric or nitric acid, it is completely decomposed, and the subsequent addition of water no longer produces a blue precipitate. Potassa, soda, and their carbonates, baryta, strontia, and caustic lime, precipitate the iron of its cyanide in the form of sesquioxide, and there is formed an alkaline or earthy cyanide, which combines with the cyanide of iron to constitute a soluble double salt. If, for example, potassa be employed, the yellow prussiate will be reproduced; and in point of fact this is the best process for obtaining that salt in a state of purity. When prussian blue is digested with red oxide of mercury and water, the blue color disappears; there is formed cyanide of mercury, which dissolves, and a clear brown precipitate remains, formed of cyanide and sesquioxide of iron.

Manufacture of Ferrocyanide of Potassium.—This operation consists, as previously stated, in heating to redness nitrogenous organic matters, such as dried blood, horn, hair, skin refuse, and other offals, along with carbonate of potassa and iron. The animal matters may either be employed in the crude state, or after being subjected to a previous calcination. The latter method is generally adopted, because it permits of extracting, by a preliminary distillation of the nitrogenous substances, a considerable quantity of carbonate of ammonia, which may be converted either into chloride of ammonium, or directly into caustic ammonia—products of so much commercial value that prussian blue is generally a mere secondary product of the manufacture of ammoniacal salts.

All the residues of the calcination, or of the distillation of animal matters, are fitted for the fabrication of prussiate of potassa, with the exception of animal black, which, in consequence of the great quantity of phosphate of lime contained in it, would produce, by calcination with the carbonate of potassa, a corresponding quantity of phosphate of potassa instead of prussian blue.

The product of the preliminary calcination of the crude materials is ten to thirteen per cent. of animal charcoal, which is finely pulverized, and mixed very intimately with pearlash of good quality, as free as possible from sulphate, in the proportions of one and a half to two parts of charcoal to one part of potassa. The latter may be dissolved in the smallest possible quantity of water, which has the advantage of separating the foreign salts, and especially the sulphate—these being insoluble in a very strong solution of potassa; this concentrated menstruum is made into a paste with the charcoal powder, and the whole is then exsiccated. In this way the potassa is made to penetrate the pores of the charcoal, and the mixture is much more intimate than can be procured by any mechanical process.

The whole is then heated in a kind of retort, until brought to a state of pasty fusion, at which it is maintained. The retort employed is of cast-iron, very thick, somewhat varying in its shape, but which in all cases should have the mouth or neck rather narrow, to admit of being easily closed up. The form most generally adopted is represented in Fig. 314; the body of the retort, *a*, is ovoidal; it is supported at the back by a projection, *b*, which rests in the wall of the furnace; the neck, *c*, is cylindrical, and is kept firm in its place

Fig. 314.

by two lateral projections, *c c*. The mouth of the retort is closed by means of the lid, *i*, and in front of the opening is the working plate, *d*, which consists of an iron or stone slab, supported externally by a bracket; *g* is the grate on which the fuel is introduced through the charging-door, *f*; *z*, the ash-pit; *h*, the vault of the furnace; and *o* the flue which conducts the products of combustion into the chimney.

The retort is about half-filled with the mixture above-mentioned, and at first it is heated gradually by charging the grate with fuel. As soon as the retort arrives at a red heat, the mouth is closed by means of the lid, *i*, and the fire is then kept up just sufficiently to maintain the same temperature. Every quarter of an hour the plate, *i*, is removed for an instant, in order to agitate the pasty mass as quickly as possible with an iron rabble. During this operation combustible gases are disengaged, which inflame at the mouth of the retort every time it is opened. The quantity of these gases diminishes as the process proceeds, and this is considered to be completed when all flame disappears. The first operation lasts, on the whole, about twelve hours, including in that period the time necessary to heat the furnace and the retort; the subsequent operations, when the mixture is introduced into the retort already heated to redness, require only eight hours.

An inconvenience which has not hitherto been satisfactorily overcome, and which considerably increases the price of prussiate of potassa, is the circumstance that the iron which enters into its composition is supplied at the expense of the retort itself. The lower part of the vessel is thus worn away, and often very unequally, so that it breaks out into holes. Hence it is necessary to give it in the first instance a thickness of one or two inches, and this requires that, in order to produce in the interior of the retort a suitable temperature, the furnace be heated to a bright red, which rapidly consumes the outside of the retort. Attempts

have been made to add directly to the mixture of animal charcoal and potassa, iron very finely divided in the shape of filings or turnings, but not hitherto with that success which was anticipated. When a hole appears in the lower part of the retort, it is turned half round on its axis, the hole is stopped up with iron cement, and the retort is thus made to serve for a new series of operations.

When the fusing process is completed, the molten mass is scooped out with an iron shovel, having a long handle, and is thrown into an iron pan, in which it is shut up and left to cool. The soluble matters are then thoroughly drained out with boiling water, and filtered through woollen cloths. The animal charcoal which remains upon the filter, possesses the property of decoloring sirups, vinegars, *et cetera*. It may also serve, when mixed with fresh animal charcoal, for another calcining operation. The clear yellow solution which passes through the filter, may either be employed directly for the preparation of prussian blue, or concentrated to the proper degree in iron boilers, and then introduced into wooden crystallizing vessels. The yellow prussiate thus obtained has still to be februated by one or two subsequent crystallizations before being sent into the market. In consequence of the great solubility of prussiate of potassa, the mother-water, or the liquid that remains after crystallization, still retains a notable quantity of that salt, together with carbonate, phosphate, and sulphate of potassa, as also the chloride, sulphide, and sulphocyanide of potassium. It is therefore employed for the direct preparation of an inferior quality of prussian blue, or concentrated by evaporation to extract from it an impure prussiate of potassa.

Mr. MUSPRATT of Liverpool, the founder of the British *alkali* trade, was one of the earliest to manufacture the yellow prussiate, which he did in Dublin in the years 1819, 1820. He found it very difficult to obtain the salt in large crystals; but this object he surmounted by mixing with every dissolved metal of prussiate one pound of sulphate of iron. The result proved most satisfactory. He was the first to use the copperas for this purpose. It is now employed often, and is further dwelt on below.

The theory of this manufacture is as follows:—The animal charcoal consists essentially of carbon, and contains, besides, a small quantity of nitrogen; when it is heated *per se* it undergoes no alteration, but when mixed with potassa and heated to redness, the affinity of the alkali for cyanogen determines the formation of the latter by means of the nitrogen and a part of the carbon contained in the animal charcoal. When, in addition to potassa, iron enters into the mixture, there is formed cyanide of iron, which, having a great affinity for the cyanide of potassium, combines with it to form a double cyanide, which is the prussiate of potassa.

Almost always, especially when the operation is arrested a little too soon, there is not a sufficient quantity of cyanide of iron formed to saturate the cyanide of potassium, which is then present in excess, and passes into the solution. To transform this excess of cyanide into ferrocyanide, before crystallizing the solution, a quantity of dissolved protosulphate of iron is poured in until a white or bluish and persistent precipitate begins to be formed.

In this reaction, a part of the cyanide of potassium is decomposed; there is formed on the one hand sulphate of potassa, and on the other cyanide of iron, which combines with the undecomposed cyanide of potassium to form an additional quantity of the yellow salt.

Dr. URE remarks that, all things considered, the manufacture of prussiate of potassa is perhaps less understood, and therefore less perfect than that of any other chemical substance of equal importance. Whether the primary materials be calcined or not, a prodigious waste invariably occurs in the manufacture, and fully two-thirds of the nitrogen existing in the animal matters are driven off and lost. More frequently, indeed, the loss amounts to three-fourths, and even this is sometimes exceeded. Woollen rags or clippings, and good American potassa or pearlash, *with an admixture of scrap-iron*, are stated by Dr. URE to have given a larger produce than any other substances within the range of his experience, though, even in this instance, two-thirds of the whole nitrogen passed away as ammonia. In general one ton of dried blood or woollen rags, with about three hundredweight of good potassa, will produce from two to two and a half hundredweight of prussiate of potassa, and a proportionate amount of sulphate of potassa. The presence of scrap iron in a proper state of subdivision, is, however, necessary to insure the above result; for when no more is supplied than that which arises accidentally from the iron pot in which the operation is carried on, scarcely half these proportions will be obtained.—*Ure*.

In 1840 a patent for an improved method of conducting the manufacture of this important salt, was taken in the name of Mr. BERRY, with a special view to avoid the loss of nitrogen incurred in the common process. For this purpose the primary matters are treated differently, so as to collect the nitrogen which escapes during the distillation, and to cause it to enter into combination with carbon, iron, and potassium—the carbonate of ammonia being made to pass through a mixture of these substances placed in iron pipes which are maintained at a red heat. The following proportions of ingredients have been found to give good results:—

	Parts.
Potassa,.....	30
Nitre,.....	10
Acetate of iron,.....	15
Charcoal or coke,.....	45 to 55
Dried blood,.....	50

The blood or animal matter is put into an iron vessel resembling a gas retort, and the other materials, mixed and dried, are put into vertical pipes with which the retort communicates. The pipes containing the absorbing mixture must be raised to a red heat before the retort containing the animal matter is heated, in order that from the commencement of the operation the decomposition of the gases may take place. The charcoal in the mixture decomposes the carbonate of ammonia which passes over, and forms bicarbide of hydrogen; at the same time it gives up part of it to the nitrogen which proceeds from the decomposed ammonia, and thereby forms cyanogen, which, in its turn, combining with the reduced potassa, forms

ferrocyanide of potassium. To obtain the most complete reaction, the charcoal should be reduced into pieces of the size of a walnut, and soaked with a solution of carbonate of potassa in urine; the solution of nitrate or acetate of iron is then poured over the heap, and when the whole has been dried by a moderate heat, it is introduced into the pipes. The gas evolved by the decomposition is inflammable when issuing from the pipes, which are fitted with gas-burners, and the color of the flame indicates the progress of the operation. When it approaches to pink, it is known that the reaction is almost complete, and that very little if any ammonia has escaped decomposition. When the jet becomes smaller and clearer, and there is a good fire under the retorts, the operation is nearly terminated. The charge must then be removed; and being at a red heat, it should be at once thrown into water in order to extinguish it rapidly, the whole being well stirred and allowed to settle. The clear liquor is then drawn off, and the residuum is subjected to successive washings by filtration. The strong solutions are evaporated and crystallized, and the prussiate is extracted according to the old process. The weaker solutions, which will not crystallize, contain carbonate of potassa; and this is extracted to be em-

Fig. 315.

ployed in the next operation, along with the residuum of charcoal and iron mixed with fresh materials.

The apparatus in which these operations are conducted, is shown in different sectional views in Figs.

Fig. 317.

Fig. 318.

315, 316, 317, and 318, in all of which the same letters refer to the same parts. Fig. 315 is a top view of the apparatus. The general arrangement is exhibited in

Fig. 316, where D is the door and G the grate of the furnace, R the retort containing the animal matters, and P one of the pipes containing the absorbing mixture. The number, the elliptical form, and the vertical position of the pipes, are shown in the other figures. The form of the tube, C, by which they are connected with the retort, is represented in Fig. 315, and also in Fig. 317 with its stopcocks, S, S'. I is an incline over which the flame passes to heat the pipes before it is permitted to play upon the bottom of the retort by withdrawing the slide, d. The products of combustion escape by a lateral passage into the chimney, C. In Fig. 317 are shown the gas-burners, G, G', with their stopcocks, S, S'. K K, Fig. 315, are covers closing the pipes. Lastly, O, Fig. 316, is an open shed or roofed space under which the pipes are emptied at the end of each operation.

The most extraordinary event in the history of this manufacture, says GRAHAM, the writer of the Great Exhibition Jury Report on the prussiates of potassa, is the attempt made a few years ago to introduce the air-process, which is of much interest both in a scientific and practical point of view. As cyanogen is rapidly converted into ammonia, the artificial formation of the former from the nitrogen of air would likewise furnish an unlimited supply of ammonia, of which the importance to agriculture could not well be over-estimated. An account of the operations which were undertaken with this view, was communicated to Professor GRAHAM by Mr. F. R. HUGHES of Borrowstowness; who states that, in 1844, his firm commenced a series of experiments upon the large scale at Newcastle, in company with Messrs. BRAMWELL, to manufacture the ferroprussiate of potassa without animal matter, substituting the nitrogen of the atmosphere for it, and continued the experiments at very great expense till the latter end of 1847. In these operations a tube or retort of fire-clay was placed in a vertical position in a furnace capable of producing an intense heat. The tube was filled with wood-charcoal, saturated with a solution of the carbonate of potassa of commerce, and dried. The mixture in this state generally contained about twenty per cent. of potassa. By means of an air-pump, the atmospheric air was drawn through the tube of alkaliized charcoal in a continuous stream from the top, and discharged below in the state of nitrogen and carbonic oxide. The alkaliized charcoal was thus found to become pretty rich in cyanide of potassium; one half of the alkali of the cyanized charcoal frequently being found, upon testing, to be in combination with cyanogen; so that when all was working well, thirty-six to forty hundredweight of prussiate of potassa were produced in a week by means of seven to eight retorts, of ten to twelve feet long in the fire, and two feet internal diameter.

There were two great drawbacks to this process; one, the immense quantity of material to be lixiviated for a small return of prussiate; the other, and by far the more important, an extraordinary waste of potassa in the process, upwards of three parts by weight being consumed in producing one of prussiate. The whole of this waste could never be properly accounted for. About one part was, of course, recovered in a state of

prussiate. It was found that another was lost in the small refuse charcoal, which could not be lixiviated to pay, and the remainder appeared to be partly combined with the bricks of the retort, and partly dissipated up the chimney.

In 1847 the experiment was abandoned after a loss of many thousand pounds; but it proved the possibility of producing large quantities of cyanide of potassium, by drawing intensely-heated nitrogen and carbonic acid gases through a mixture of potassa and charcoal, with the difficulty of carrying this out as a manufacturing process, from the great waste of potassa.

Preparation of Prussian Blue.—The theory of the fabrication of prussian blue has been already stated; it only remains to enter into some practical details on this subject.

A distinction is made between the pure or *Paris blues*, and those that are mixed with alumina, or *Berlin blues*. The choice of the original raw materials naturally depends on the beauty and price of the article which is intended to be manufactured. For the finer kinds, one employs prussiate of potassa which has been purified by several successive crystallizations; for the common blues, the crude solution of prussiate of potassa is almost always taken; lastly, for inferior varieties, the mother-waters of the manufacture of the crystallized prussiate are used.

The salt of iron almost exclusively employed is the protosulphate. It should not contain copper, which would give rise to a reddish-brown precipitate very injurious to the color of the prussian blue. The presence of copper is easily detected by dissolving in water a little of the sulphate for trial, acidulating the liquor with sulphuric acid, and dipping into it a well-cleaned plate of iron; if copper is present, it will be reduced, and will form a red metallic coating on the surface of the iron plate. Cupriforous protosulphate may be purified, and all the copper precipitated, by dissolving it in water, and boiling it for some time with a little sulphuric acid and old scrap-iron or turnings; but this process entails considerable expense, and it is better in all cases to procure sulphate of iron which is sent into the market free from copper—a precaution attended with little difficulty. Before employing this sulphate, it is left exposed to the air till it acquires a reddish-brown color. Perhaps it would be still better to employ for the preparation of the finest blues sesquinitrate of iron, which furnishes a blue of such great beauty that the additional expense incurred in its manufacture would be more than compensated by the quality of the product obtained.

The crude solution of prussiate of potassa, and even the prussiate purified by a single crystallization, still contain, as has been stated, more or less carbonate of potassa, so that, besides the prussian blue, there is precipitated at the same time yellow oxide of iron, which deteriorates its tint. To obviate this inconvenience, the carbonate of potassa is neutralized by sulphuric acid, which may be added either to the solution of prussiate of potassa or to that of the protosulphate of iron. In the manufacture of the common Berlin blues, the carbonate of potassa is neutralized by alum; there results a precipitate of alumina, which mixes intimately with the prussian blue, and greatly augments

its weight without notably weakening the tint when the quantity is not very considerable. For this purpose, the requisite quantity of alum, previously determined by experiment, is dissolved in the solution of sulphate of iron; then the whole is poured little by little, and taking care to agitate continually, into the solution of prussiate of potassa, which gives a precipitate of a more or less dark blue that soon settles down. The supernatant liquid is then decanted, its place is supplied by pure water, it is again shaken, allowed to deposit, decanted, and is thus subjected to a series of successive washings, in order to abstract the soluble matters, and to deepen the color of the blue by the absorption of the oxygen contained in the water. The residue of the washing is then thrown on cloth filters, where it is left to drain; it is afterwards subjected to moderate pressure, and finally divided into small bricks or cakes, which are left to dry in the shade.

As prussian blue, when once dried, is difficult to reduce again to the state of extreme division which it possessed in the moist state, it is often sold and employed *in paste*—that is to say, *not dried*—especially for the manufacture of paper-hangings, *et cetera*.

A good article, says the late Dr. URE, is known by the following tests:—It feels light in the hand, adheres to the tongue, has a dark lively blue color, and gives a smooth deep trace; it should not effervesce with acids, as when sophisticated with chalk; nor become pasty with boiling water, as when adulterated with starch. The Paris blue, prepared without alum, with a sesquisalt of iron, displays, when rubbed, a copper-red lustre, like indigo. Prussian blue, degraded in its color by an admixture of free oxide of iron, may be improved by digestion in dilute sulphuric or hydrochloric acid, washing and drying. Its relative richness in the real ferrocyanide of iron may be estimated by the quantity of potassa or soda which a given quantity of it requires to destroy its blue color.

The precipitate formed by adding a solution of ferridcyanide of potassium—the red prussiate—to a protosalt of iron, constitutes the color known in commerce as *Turnbull's blue*. It is produced by the substitution of three atoms of iron for the three of potassium in the red salt. Its color is a little brighter than common prussian blue. It is prepared in the arts by adding to a solution of copperas a mixture of yellow prussiate of potassa and chloroxide of sodium.

Prussian blue is employed as a water color, but not in oil-painting. In 1837, Messrs. STEPHEN and NAX of London took out a patent for a process by which it can be obtained in solution, and employed not only in calico-printing, but also as a tinctorial agent, thereby greatly extending its application. The process consists in first digesting the prussian blue of commerce, for a period of twenty-four to forty-eight hours, with concentrated hydrochloric or sulphuric acid, and afterwards diluting the mixture with its own weight of water. It is then carefully washed, by decantation, with pure water, in order to remove all the acid; and, after being washed a second time on a filter, the residue is dried, and brayed in a mortar with oxalic acid. The resulting compound is found to be soluble in water.

The insufficiency of the description of this process which is given in the specification, and the absence of details with reference to the quantities of the materials to be employed, and the precautions necessary in the manipulation, induced M. KARMARSCH, a few years ago, to institute a series of experiments on this subject leading to the following results:—

1. The preliminary treatment of the prussian blue with hydrochloric or sulphuric acid, is attended with the advantages of requiring a much smaller quantity of oxalic acid to render the blue soluble; of causing the blue to keep longer without depositing any precipitate, which infallibly happens when it has not undergone the preliminary treatment; and, lastly, of rendering the blue soluble in a much smaller quantity of water, which permits of obtaining a more concentrated solution.

2. The quantity of oxalic acid necessary to determine the solution of the prussian blue is small; an excess of this acid, instead of increasing, diminishes its solubility in water.

3. The combination of prussian blue and oxalic acid is not soluble in water in all proportions; when the quantity of water is not sufficient, a portion of the color remains undissolved in the form of a dark-blue slime.

4. The most suitable proportions for obtaining a concentrated soluble blue, susceptible of being filtered without residue, and of keeping a long time without giving any deposit, are—eight parts of prussian blue treated with sulphuric acid, then well brayed with one part of oxalic acid, and dissolved in two hundred and fifty-six parts of water.

Physiological Effects.—Iron is probably inert, or only acts mechanically, so long as it retains its metallic form; but it readily oxidises in the alimentary canal, and thereby acquires medicinal power. As acids promote this chemical change, acid wines and fruits assist in rendering the metal active, while alkalies and their carbonates have an opposite effect. The oxidation of the iron is attended with the evolution of hydrogen gas, which gives rise to unpleasant eructations. If sulphur be taken along with iron, sulphide of hydrogen is developed. Like the ferruginous preparations generally, the internal employment of iron causes blackening of the stools, owing to the formation of the hydrated sulphide of iron. It is interesting to remark here, that iron is one of the few metals which by oxidisement *is not rendered more or less poisonous*.

The *local* effects of the sulphate, nitrate, and sesquichloride of iron, are those of caustics and irritants, and these preparations accordingly rank amongst poisons.

Most of the ferruginous preparations are astringent; that is, they constrict the parts with which they are in contact, and thereby diminish secretions and check sanguineous discharges. Thus, when swallowed, they repress the secretions and exhalation of the gastro-intestinal membrane, and thereby render the alvine evacuations more solid, and even occasion constipation. The sulphate, nitrate, and sesquichloride of iron, are the most powerful of the ferruginous astringents. Administered in large quantities, or when the alimentary canal is in an irritable condition, all the compounds

of iron are liable to excite heat, or weight and uneasiness at the præcordia, nausea, and even vomiting, and sometimes purging. The oxides and the carbonate of iron are very mild topical agents.

Before the chalybeates can produce constitutional effects, they must become absorbed. Under their use the blood frequently acquires a more scarlet hue, owing to an increase in the number of its coloring particles. TIEDEMAN and GMELIN have detected it in the serum of the blood of the portal and mesenteric veins of horses and dogs, to whom they administered either the sulphate or chloride. Occasionally, too, iron has been found in the urine.

The constitutional effects of iron are best observed in anæmia. If, in this condition of system, chalybeates be administered, the appetite increases, digestion is promoted, the pulse becomes fuller and stronger, the skin assumes its natural hue, the lips and cheeks become more florid, the temperature of the body is augmented, the oedema disappears, and the muscular strength is greatly increased. These results are mainly due to the alteration in the composition of the blood. This is shown by the healthy vermilion tint which the patient acquires, as well as by the chemical analysis of the blood.

Iron filings are employed as an antidote in poisoning by the soluble salts of copper and mercury. The iron reduces them to the metallic state. The following formula explains the action of iron on a solution of sulphate of copper:— $\text{Cu O, SO}_3 + \text{Fe} = \text{Cu} + \text{Fe O, SO}_3$.

Sesquioxide of iron is termed alterative, tonic, and emmenagogue. Its obvious effects on the body, however, are very slight.

Hydrated sesquioxide of iron has been employed as an antidote in poisoning by arsenious acid, a basic insoluble arseniate being formed. BUNSEN and BERTHOLD were the first to assert the antidotal powers of this preparation. Their statements were confirmed by the experiments of SOUBEIRAN and MIQUEL, of ORFILA and LESNEUR, *et cetera*.

Sulphide of iron in cutaneous maladies of a scrofulous character has proved a valuable alterative, and more serviceable than iodine. It appeared to be less irritating, and not so liable to excite suppuration in scrofulous swellings. BRIET gave it in obstinate lichen agrius.

Sulphate of Iron.—This salt acts locally as a powerful astringent, and when employed in a concentrated form, as an irritant. The latter effect depends on its chemical action on the organic constituents, albumen, *et cetera*, of the tissues. The remote effects of sulphate of iron are analogous to those of other ferruginous compounds, which have been already described.

Swallowed in *small doses*, it has an astringent operation on the gastro-intestinal mucous membrane, and thereby diminishes the quantity of fluids secreted or exhaled; hence its continued use causes constipation. It blackens the stools like other compounds of iron. It becomes absorbed, and operates on the system as a tonic, stimulant, emmenagogue, and astringent. In *excessive doses* it acts as an irritant poison. A girl took, as an emmenagogue an ounce of it in beer, and was seized in consequence with colic pains, constant

vomiting, and purging for seven hours. Mucilaginous and oily drinks soon cured her.

It is employed in lump, powder, or solution, as a styptic to check bleeding from numerous small vessels. The sesquinitrate, acetate, iodide, citrate, *et cetera*, are employed daily in medicine also. Their effects are similar to the other ferruginous salts.

The general indications for the use of the iron compounds are debility, feebleness, and inertia of the different organs of the body; atony, marked by a soft, lax, or flabby condition of the solids; and defect of the red corpuscles of the blood; as where there is a general deficiency of this fluid—*anæmia*; *oligæmia*, or a watery condition of it—*hydremia*, *serous crasis*; *leucophlegmatic temperament*.

The contra-indications are the reverse of these; great strength and activity of organs, excessive tonicity, characterized by a firm and tense condition of the solids, and redundancy of the red corpuscles of the blood,—as in general excess of the blood-plethora, in fever, in acute inflammation, in the sanguine temperament. To these may be added congestion, or a tendency thereto, of important organs—especially of the brain and lungs—and intestinal irritation.—*Pereira*.

Statistics.—At the Great Exhibition, the prussiates of potassa, which invariably accompany the manufacture of prussian blue, were exhibited of great purity and beauty, by several manufacturers, particularly Messrs. T. BRAMWELL and Company, of Newcastle; the Hurler and Campsie Alum Company, of Glasgow; the Bouxwiller Mining Company, of France; C. SCHLIPPE, of Russia; and ALEXANDER BRUSGHIN, also of Russia.

The prussiate made by Mr. MUSPRATT in 1820, in Ireland, and that manufactured in England, sold for five to six shillings the pound; but for some years previously a weak solution of the salt, or of the fluxed mass of animal matter and potassa, had been sold at one shilling per gallon. The process of manufacture, so far as regards the materials used and the furnaces employed, is still essentially the same as it was fifty years ago; but in consequence of agitating the fluxed mass by machinery in closed pits, introduced at Glasgow by the late CHARLES MACINTOSH in 1824, and other minor improvements in the manipulation, the production of prussiate from the same quantity of animal matter has been increased threefold. The rapid progress of this manufacture will appear from the following estimate of the annual production in the United Kingdom:—

ANNUAL PRODUCTION.

From 1825—1830 about	10 tons at 5s. 0d. per pound.
“ 1830—1835 “	40 “ 2s. 6d. “
“ 1835—1840 “	200 “ 1s. 4d. “
“ 1840—1845 “	700 “ 1s. 4d. “
“ 1845—1850 “	1040 “ 1s. 3d. “

There are eleven prussiate works in the United Kingdom, of which the aggregate produce is, when the salt is in demand, about twenty tons per week. The two largest factories are those of Messrs. BRAMWELL and the Hurler and Campsie Alum Company. The value of the annual product is estimated at one hundred and forty-five thousand six hundred pounds sterling.

The manufactory of Messrs. BRAMWELL was established about eighty years ago, at which time prussian blue only was made in it, a considerable quantity of which was sent annually to China, and used by the Chinese, it was believed, for coloring green teas; a Spring shipment was always made of about two thousand pounds sterling in value, which was often followed by another in Autumn. It was first sold at two guineas per pound, made up in neatly finished one-pound packages, but had fallen in 1815 to ten shillings and sixpence, and about 1820 to two shillings and sixpence. For the last ten or fifteen years the price of prussian blue has averaged one shilling and ninepence per pound.

The Editor begs to express his thanks to Mr. GEORGE BLAIR of Glasgow, for his kind assistance in the compilation of this and other articles.

LEAD.—*Plomb*, French; *Blei*, German; *Plumbum*, Latin.—This metal is of a bluish-grey color, with a strong metallic lustre when recently cut; but when exposed for a short time, its brilliancy disappears, and gives place to a very thin coating of basic carbonate of the oxide of lead. Owing to its softness it leaves a streak on white paper, and may be easily cut with a knife. It is highly malleable and ductile, but is deficient in tenacity, when compared with all the other ductile metals; a wire one-tenth of an inch in diameter being capable of supporting a weight of only thirty pounds. It may be easily rolled out into moderately thin sheets and likewise drawn into wire; but from its want of tenacity, the latter operation cannot be performed so freely as with gold, platinum, silver, copper, or iron. The specific gravity of lead is 11·445 when subjected to pressure, as in rolling; but in mass it is somewhat less, being 11·350; its chemical symbol, is *Pb*—derived from the Latin term *plumbum*—and its combining equivalent 104.

HISTORICAL NOTICE.—In the articles on COPPER and GOLD it has been stated that these metals were brought into use at a very early date, and it seems probable that *lead* was known at least as early as copper. Mention is repeatedly made of this metal in the book of Exodus, and in various other parts of holy writ. It would appear from BECKMANN, indeed, that some doubt exists as to the true meaning of the word rendered *lead* by the translators of the scriptures, although he does not deny its very great antiquity. The Phenician colony in Spain drew largely upon Britain for this metal, and also for tin; and it is stated by CAMDEN that lead was obtained from Cornwall, Cumberland, and other places in England, before the Christian era. During the incursions of the Romans, it is certain that it formed an important article of commercial interest; and that it was used in considerable abundance, may be inferred from the specimens which have been discovered from time to time, bearing Latin inscriptions. After the departure of the Romans, the Saxons continued to work the lead mines, one of which, near Castleton, was dedicated to Odin. That the mines near Wirksworth were worked before the year 714, appears from the discovery of a sarcophagus of lead, lined with linen prepared in that locality. In the year 835, the lead mines of Wirksworth were surrendered to one

HUMBERT, on payment of an annual rent in that metal to the value of three hundred shillings, for the use of Christ Church, Canterbury. In Doomsday-book the mines in the Peak, and the Wapentake of Wirksworth, are referred to as the peculiar property of the sovereign, and those of Derbyshire, were designated *The King's Field*. In the ages of alchemy, lead was regarded as a semi-metal, and bore the name of *Saturn*, owing probably to its bluish-grey color.

SOURCES.—Lead is found in various combinations in mineral strata, and on rare occasions in the native state. Kerry in Ireland, Carthage in Spain, and Alston Moor in Cumberland, have afforded specimens of lead in this state, sometimes associated with galena, and at other times disseminated therewith in an argillaceous or a silicious rock.

The ores of lead are numerous, but are found in very unequal proportions; that from which the metal is extracted being for the most part galena, or bisulphide of lead. The most important of them are the oxide of lead or massicot, chloride of lead, bisulphide of lead or galena, carbonate, phosphate, sulphate, arseniate, and chromate of lead.

Oxide of lead may be regarded as being derived from the sulphide in the presence of other bodies which exhibit an affinity for the sulphur. It is found only in small quantities, and usually associated with galena.

Chloride of lead is another very rare natural combination, which is found in small quantity in the Mendip hills, generally deposited upon a matrix of binocide of manganese, and crystallized in rectangular prisms, with the angles and edges sometimes truncated.

Carbonate of lead—sparry lead ore—is remarkable for its transparency and lustre when in its purity. Several varieties of this ore are known. It is found in the form of acicular crystals, in compact masses, and often presenting a fibrous, lamellar, and earthy appearance. They all, with the exception of the earthy species, possess a peculiar lustre, like that of white lead. Earthy carbonate of lead presents several shades of color—brown, green, or blue—dependent upon the nature of the metal associated with it. The mineral is very brittle, and its fracture has a waved conchoidal appearance. Its specific gravity varies from 6 to 6·7.

It is met with in comparatively small quantities and is confined to a few localities. At Leadhills and Wanlockhead, two well-known Scotch localities yielding this metal, the carbonate occurs with other minerals, particularly with phosphate, sulphate, and other combinations of lead, accompanying galena in transition-slate. It occurs in the mines at Alston Moor, at Keswick, and in some parts of Cornwall, particularly at the mine of St. Minvers. In many of the continental mines, particularly in Saxony and the Hartz, it is eviscerated. Being a mineral rich in lead, it is easily smelted. A black species of carbonate of lead is sometimes found, which owes its characteristic color to small particles of galena being disseminated throughout the crystals. The most extensive deposit of carbonate hitherto discovered is that at the mine à la Motte, Missouri, in America, where millions of pounds of metal have been extracted from this mineral. When treated before the blow-pipe on charcoal, it decrepi-

tates and changes color to a yellow, then becomes red, and finally is reduced to metal in the inner flame, the charcoal being coated with litharge. Heated with fluxes it gives rise to a diaphanous glass. Acids readily act upon it; carbonic acid being evolved with effervescence, and a lead salt of the acid being produced.

The following analyses have been made of this mineral:—

	Crystals of carbonate of lead from			
	Lead Hills. Klaproth.	Zellerfeld. Westrumb.	Nertschinsk. John.	Teesdale. J. A. Phillips.
Protoxide of lead,...	82·00	81·20	84·5	83·50
Carbonic acid,.....	16·00	16·00	15·5	16·50
Lime,.....	—	0·90	—	—
Iron,.....	—	0·30	—	—
Loss,.....	2·00	1·60	—	—
	100·00	100·00	100·0	100·00

The formula by which its composition may be expressed is PbO CO_2 .

Sulphate of lead is a mineral associated with carbonate in the mines of the Leadhills and Wanlockhead in Dumfries-shire, Scotland. It is found in quantities in Parry's Mine in Anglesea, and at Mellanoweth in Cornwall, where it is associated with galena, from which it gives evident indications of being produced by oxidation. Sulphate of lead has been found at Clausthal and Zellerfeld, in the Hartz, and various other mines on the Continent; although the quantity is too small to attract the attention of the metallurgist.

Its color is sometimes grey or yellowish, frequently tinged blue or green by oxide of copper; its crystallized form is that of a rhombic prism, with dihedral summits; but when the crystals are short, they assume the form of the octahedron. Generally the crystals are possessed of the same transparency and adamantine lustre as those of the carbonate, so that from appearance the two may be often confounded. With acids, however, the sulphate of lead affords no marked reaction, and this forms one distinguishing feature of the two compounds.

Before the blow-pipe the sulphate decrepitates, and then melts; in the oxidising flame it fuses into a transparent globule, which on hardening turns milk-white; in the inner flame it effervesces, owing to the evolution of sulphurous acid, and is quickly reduced to the metallic state. Samples of this mineral afforded to KLAPROTH the annexed composition.

	Anglesea.	Wanlockhead.
Protoxide of lead,.....	71·0	70·50
Sulphuric acid,.....	24·8	25·75
Water,.....	2·0	2·25
Loss,.....	2·2	1·50
	100·0	100·00

Its density has been determined by STROMEYER, and found to be between 6·23 and 6·3, and its chemical symbol in the pure state, is PbO SO_3 .

Phosphate of lead is a mineral of rare occurrence, although it is met with in many of the lead mines of Cornwall, and at the Lead Hills and Wanlockhead in Scotland. It crystallizes in hexagonal prisms, which are sometimes transparent, though more generally of a bright green, or brown, and sometimes of a fine orange color, derived from the presence of a small quantity of chromate of lead. Before the blow-

pipe, on charcoal, it melts in the outer flame into a globule which crystallizes on cooling, and becomes brown; in the reducing flame, the lead appears bluish, is luminous while hot, and on cooling crystallizes with large facets of a lighter color. Its specific gravity is from 6.5 to 7.0, and its centesimal composition, according to the analyses of KARSTEN and WÖHLER, as follows:—

	From Bohemia.	From Cornwall.
Phosphate of lead,	89.268	89.110
Chloride of lead,	9.918	10.074
Phosphate of lime,	0.771	0.682
Fluoride of calcium,	0.137	0.130
	100.094	99.996
		From Zschopau.
		Wöhler.
Oxide of lead,		82.29
Phosphoric acid,		15.73
Chlorine,		1.98
		100.00

Chromate of lead is a very beautiful mineral, of a deep or hyacinth red color, and crystallized in oblique rhombic prisms, the cleavages of which show it to be translucent on the edges; it possesses an adamantine lustre, and gives an orange-yellow streak. It is, however, very rare, being found only in the Brazils, and at Beresof in Siberia. An artificially-prepared chromate of lead, forms the *chrome-yellow* of painters. Specific gravity of the native mineral is about 6, and its composition corresponds with the formula PbO, CrO_3 .

Sulphide of lead—*Galena*; *Bleiglanz*, German; *Plomb Sulfuré*, French.—This is the most diffuse, and at the same time the most abundant ore of lead known; it forms veins and beds both in the primary and secondary rocks. At Freyberg in Saxony, it is found in veins in gneiss; at Sala in Sweden, it is met with in the primitive limestone; and at Clausthal and Newdorf in the Hartz, Przibram in Bohemia, and several other districts, clay-slate forms the repository of the metallic veins. The grauwacke of Dumfries-shire and the killas of Cornwall are traversed by lodes in which the mineral is contained; whilst in Derbyshire, Cumberland, and the other northern districts of England, and also several other localities on the Continent, it is extracted from amidst the mountain limestone. Valuable deposits of galena are worked at many other places besides those mentioned above. Wales and Ireland afford large quantities of the mineral. In several of the French departments it is found in considerable abundance, especially at Huelgöet and Poullaouen in Brittany, at Pontgil and Puy-de-Dome, and Villefort in the department of Lozère. Catalonia, Grenada, and the granite hills of Linares in Spain afford sulphide of lead. Extensive deposits of galena occur in the United States, particularly in Missouri, Illinois, Iowa, and Wisconsin.

Galena frequently appears under different forms, and is variable in its composition. Usually, it has a metallic lustre, and a leaden-grey or blackish-grey color. The primary form of its crystal is the cube; but it occurs in the form of octahedra and its varieties. Its structure is lamellar, and its cleavage, which is highly perfect, parallel to the planes of the cube. The specific gravity of the mineral is 7.5 to 7.7, and, when pure, it is composed of lead and sulphur, in the ratio of 86.55

of lead, and 13.45 of sulphur. The amount of lead, however, is subject to variation, owing to the presence of more or less silver, which is invariably associated with it, and also that of other metals, such as antimony, zinc, iron, copper, and arsenic. The following analyses of samples of galena show its usual composition:—

	Brudant.	Westrumb.	Thomson.
Lead,	79.6	83.00	85.13
Sulphur,	13.4	16.41	13.02
Silver,	7.0	traces	—
Loss,	—	0.59	1.85
	100.0	100.00	100.00

It may be remarked here that the presence of silver, notwithstanding the proportion may be so large as the one-fifth of the whole, does not materially alter the external characters of the galena; but when silver is present in that amount, other metals, such as antimony and bismuth, are also contained in the mineral in appreciable quantities. The richest silver-lead ore is that found at Tarnowitz in Silesia, which contains about a fifth of its whole weight of silver; the usual proportion of this metal is, however, from 0.0001 to 0.003 per cent., and the ore is designated by the Germans *Weisgültigerz*.

The principal varieties of this mineral are *specular galena* and *blue lead*. The former is found in some of the Derbyshire mines, where it forms very thin coatings on the walls of the veins, so as to give the latter the appearance of looking-glasses. On this account it is designated *slickenside*; it explodes with a loud report when accidentally scratched in the mine. *Blue lead* is a kind of galena which is of frequent occurrence, having a hue between leaden-grey and indigo-blue. Other compound sulphides of lead with sulphides of silver, antimony, and bismuth are known; but these will be referred to afterwards.

Galena is a protosulphide, and is therefore represented by the symbol PbS .

PREPARATION OF PURE LEAD.—As prepared from the ores of lead by the metallurgical processes in ordinary use, and which will be described presently, the lead of commerce is impregnated with other metals in small quantity, such as silver and tin, and occasionally traces of arsenic, antimony, copper, iron, and zinc, when the ores operated upon contain these metals. To obtain chemically pure lead, it is necessary to work upon the ordinary product with such reagents as will cause the separation of these metals. The method recommended is to heat the nitrate of oxide of lead in a crucible, and to reduce the litharge so produced with charcoal in a covered crucible, or with hydrogen gas at a red heat, presupposing that the lead salt is quite pure; but should it contain nitrates of other metals, such as silver and the like, these will pass into the reduced lead. This fact has been repeatedly proved, and even when great care has been bestowed upon the preparation of the lead salts with a view to their reduction, traces of silver have been detected in the resulting metal.

When lead absolutely free from silver is required, it is necessary to dissolve the lead of commerce in nitric acid, and to crystallize the nitrate thus formed by

concentrating the clear solution; then precipitate the metallic base from the fluid with sulphuric acid; wash well the insoluble sulphate of lead, and finally reduce the latter by fluxing it with pure carbonate of soda and ground resin in a lined Hessian crucible. The button of metal which is thus obtained may be relied upon as being *absolutely pure*. The nitric acid has the effect of precipitating any tin and antimony as oxides; and during the subsequent crystallization of the lead salt from the clear filtered liquid, much of the silver will be left in the mother liquor, and the last traces of this metal are got rid of by precipitating the lead as a sulphate, and washing thoroughly. A very pure lead, so far as freedom from silver is concerned, is obtained by reducing the litharge which results from the furnaces of cupellation, as those at Freiberg in Saxony, and this is well adapted for the assayer's use. It may also be prepared by electrical agency, as by introducing a bar of zinc or iron into a solution of nitrate or acetate of lead carefully prepared; but by this means absolute purity is not insured, as the easily reducible silver, if contained in the salt operated upon, will likewise be precipitated.

CHEMICAL PROPERTIES OF LEAD.—The affinity of lead for oxygen is very great, even at ordinary temperatures; but this is increased when its temperature is elevated. Under the latter condition, it burns in the air with a bluish-white light, and affords oxide of lead or litharge. FARADAY has shown, that when finely divided, this metal is more inflammable than gunpowder. Nitric acid acts energetically upon lead, converting it into an oxysalt of this acid; acetic acid likewise dissolves it, but sulphuric and hydrochloric acids have only a feeble action upon it, especially in the cold. With the aid of heat, however, concentrated sulphuric acid dissolves it with the evolution of hydrogen.

At a red heat, hydrochloric acid vapor acts upon lead, producing a chloride of the metal and liberating hydrogen. This metal is capable of uniting with all the non-metallic elements, with the exception of hydrogen, borium, silicium, and carbon; with all the metals, except iron, it enters readily into combination, giving alloys which are of considerable importance in the arts, and some of which have been described under the heads, *ANTIMONY, BISMUTH, et cetera*. Its oxides, which are numerous, are employed for various useful purposes, and one of them, the protoxide, commonly known as litharge, readily combines with all the oxygen acids, forming salts, some of which are used in the arts to a very large extent. In the form of sheet lead and lead piping, this metal is applied to a great variety of purposes. To the metallurgist it offers a ready and advantageous means of obtaining silver and gold in their purity, by alloying them with it, and subsequently removing the lead from the compound metal by cupellation.

PRINCIPAL LEAD MINES.—Before entering upon the details of the processes involved in the production of metallic lead from the ores, it may not be uninteresting to lay before the reader the chief mines producing galena, and some of the circumstances connected with them, as stated by URE.—The principal

mines at present worked in the world are the following:—

1. Poullaouen and Huelgöet, near Cairhaix in France, department of Finisterre, being veins of galena, which traverse a clay-slate resting upon granite. They have been in operation for upwards of three centuries; the workings penetrate to a depth of three hundred yards, and in 1816 furnished five hundred tons of lead per annum, out of which one thousand and thirty-four avoirdupois pounds of silver were extracted.

2. At Villefort and Viallaz, department of the Lozere, are mines of this ore, said to produce one hundred tons of lead, with eight hundred and eighty avoirdupois pounds of silver.

3. At Pezey and Macot, to the East of Montiers in Savoy, a galena mine exists in talc-schist, which produces annually two hundred tons of lead, and about twelve hundred and thirty pounds avoirdupois of silver.

4. The mine of Vedrin, near Namur, in the Low Countries is opened upon a vein of galena traversing compact limestone of a transition district.

5. In Saxony the galena mines are so rich in silver as to cause the lead to be regarded as a secondary product, or entirely overlooked.

6. The lead mines of the Hartz have been likewise considered as silver ores.

7. Those of Bleiberg, on the Eifel, are of the same description.

8. The galena mines of Bleiberg and Vallech in Corinthia, in compact limestone.

9. In Bohemia to the South-west of Prague.

10. The mines of Joachimsthal and Bleistadt, on the Southern slope of the Erzgebirge, produce argentiferous galena.

11. There are numerous lead mines in Spain, the most important of which are those in the granite hills of Linarès, upon the Southern slope of the Sierra Morena, and in the district of the small town of Canjagar. Enormous masses of galena are extracted sometimes from the mines of Linarès. There are mines of sulphide of lead in Catalonia, Grenada, Murcia, and Almeria, but the ore of the last locality is worked for the silver it contains.

12. The lead mines of Sweden are very argentiferous, and, like the last mentioned, are worked to extract the silver.

13. In the district of Daouria the lead mines are numerous and rich, lying in a transition limestone which rests on primitive rocks; their lead is neglected on account of the silver.

14. Great Britain is, of all countries in the world, that which annually produces the largest quantity of lead. According to M. VILLEFOSSE, in his *Richesse Minérale* published in 1819, this kingdom had furnished twelve thousand five hundred tons of lead, being more than the rest of Europe produced; it appears, however, from more recent documents, that the above estimate is too low. Mr. TAYLOR in 1822 rated the total produce of the United Kingdom per annum at thirty-one thousand nine hundred tons, a quantity fully two and a half times greater than that stated by VILLEFOSSE. TAYLOR distributed this product among the different districts as follows:—

	Tons.
Wales—Flintshire and Denbighshire,	7,500
Scotland—in transition-grauwacke,	2,800
Durham, Cumberland and Yorkshire—in carboni- ferous lime	19,000
Derbyshire—probably in carboniferous lime,	1,000
Shropshire,	800
Devon and Cornwall—transition and primitive rocks,	800
Total,	31,900

Hence it may be seen, that the adjacent parts of the counties of Durham and York furnish of themselves nearly three-fifths of the total product.

In 1835 the entire quantity was estimated by TAYLOR at 46,112 tons, of which 19,626 tons were furnished by Northumberland, Durham and Cumberland; the mines of Mr. BEAUMONT of themselves yielding ten thousand tons. The annexed table shows the increase in 1847:

	Lead Ore, Tons.	Lead Tons
England,	59,614½	39,507½
Wales,	18,147½	12,294
Ireland,	2,251	1,380
Scotland,	1,159	822½
Isle of Man,	2,575	1,699
	83,747	55,703

15. In the United States, the most remarkable lead region—and, according to BOOTH, probably the largest in the known world—where the galena is disseminated in beds of greater or less extent, is in Wisconsin, Iowa, Illinois, Missouri, and Kentucky.

The former three may be regarded as a distinct region of ninety miles from East to West, and sixty miles from North to South. Another district is in Missouri, to the South of the river so named, about eighty miles North and South, and fifty miles East and West. The lower part of Illinois, and part of Kentucky, appears to be a third district. In the first the lead found is very pure, and it is remarkable besides for the enormous crystals of galena which it produces; the second district gives often a less pure lead, which is largely associated with very pure barytic minerals; and in the third, much of the galena contains sulphide of antimony. Although extensively explored, this immense metallic region of the Mississippi valley remains to be fully developed. The best argentiferous vein yet opened in the United States, is probably that in Davidson County, North Carolina.

PRELIMINARY OPERATIONS.—Rarely is galena found of such purity as to be at once in a fit state for the action of the fire; it is generally compounded with the stony substances of the strata in which the deposit exists, and also with other minerals of a different nature. The crude product raised from the mine is, therefore, submitted to various processes of dressing, to bring it to an average standard richness. In England these preliminary operations are divided into three classes, namely, *the sorting and cleansing of the ore, the grinding, and the washing.*

Sorting and Cleansing the Ore.—At several of the British mines this operation is performed at the mouth of the mine, by the aid of sieves constructed of iron wire, the strands running parallel at an inch distance, thus forming openings one inch square. The material is thus separated into two batches, and, by using finer gauzes, into more varieties. Sometimes the clay, or

mud, is removed from the ore by placing it on a sieve with small meshes and agitating the whole in water. In many parts of Derbyshire, however, the ore is merely stirred about with a shovel in a trough filled with water; but this method, which is termed the *standing buddle* system, is obviously very imperfect. Another apparatus, called the *running buddle*, serves at once to sort and cleanse the ore. It is similar to the inclined plane used for copper ore. This contrivance, which was formerly the only one in general use at Alston Moor, has been supplanted by another called the *grate*. This is a grid constructed of iron bars one inch thick, and twenty-four to thirty inches long; these are fixed parallel to one another, and horizontally, at a distance of one inch apart. A wooden canal above the grate, conducts a stream of water over its middle, and an inclined plane set beneath it, and leading to a hemispherical basin, serves to recover the metallic powder which is detached from the mass.

Grinding.—After assorting the ore it is crushed to fine powder. Formerly the *bucker* was in frequent request, but is now giving place to the crushing machine, which effects a considerable saving in time and labor, and is, therefore, coming very rapidly into general use. This machine is represented in the annexed drawing—Fig. 319—the description of which is taken from the latest edition of URE's excellent Dictionary. It is composed of one pair of fluted cylinders, x x, and

Fig. 319.

of two pair of smooth cylinders, z z, z' z', which are immediately used for crushing the ore. The two cylinders of each of the three pair turn simultaneously in an inverse direction, by means of two toothed wheels upon the shaft of every cylinder, which work by pairs in one another. Motion is communicated by a water-wheel, the circumference of which is represented by a a a. One of the fluted cylinders is placed on the prolongation of the shaft of this wheel, and which carries besides, a cast-iron toothed wheel, gearing into two others, e e, fixed upon the ends of the two smooth

cylinders. Above the fluted cylinders is placed a hopper from which the ore with which it is charged from the waggon, A, and which advance upon tramways, till they come directly over the hopper; their contents are emptied through a trap-hole in their bottom. Below the hopper there is a small bucket called a shoe, in which the ore is shaken down, and which throws it without ceasing upon the cylinders, in consequence of the constant jolts given to it by a crank-rod attached to it and moved by the teeth of the wheel, *m*. The shoe is so regulated, that too much ore can never fall upon the cylinders so as to obstruct their movements. A small stream of water which is conducted into the shoe, spreads over the cylinders and prevents them from getting overheated. After the ore has passed between the fluted rollers, it falls upon the inclined planes, *N N*, which turn it over to one or other of the pair of smooth rollers.

These are the essential parts of this machine; they are made of iron, and the smooth ones are case-hardened, or *chilled*, by being cast in iron moulds. The gudgeons of both kinds move upon brass bushes, fixed upon iron supports, *x*, made fast by bolts to the strong wood-work basis of the whole machine. Each of the horizontal bars has an oblong slot, at one of whose ends is solidly fixed one of the plummer-blocks or bearers of one of the cylinders, *f*, and in the rest of the slot the plummer-block of the other cylinder, *g*, slides—a construction which permits the two cylinders to come into contact, or to recede to such a distance as circumstances may require. The movable cylinder is approximated to the fixed one by means of the iron levers, *H H*, which carry at their ends the weights, *P*, and rest upon wedges, *M*, which may be slid on the inclined plane, *s*. These wedges then press the iron bar, *O*, and make it approach the movable cylinder, by moving the plummer-block that supports its axis. With such an arrangement, should very large or hard pieces of ore fall between the cylinders, one of the rollers would recede, and let the piece pass without doing any injury to the mechanism.

Besides the three pair of cylinders which constitute essentially each crushing machine, there is sometimes a fourth which serves to crush the ore when not in large fragments; for example—the moderately rich pieces, called cuttings, and the poorer kinds or chats produced by the first sifting. The cylinders composing that accessory piece, which, on account of their ordinary use are called *chats-rollers*, are smooth and similar to *z z z' z'* in the foregoing figure. One of them is usually placed upon the prolongation of the shaft of the water-wheel, at the opposite side of the principal machine; and the other which is placed alongside, receives its motion from the first by means of toothed wheel-work. The ordinary stamping process is in some places combined with the use of the crushing rollers, especially if the gangue be too hard for the latter to grind.

Washing.—After the operation of grinding comes the process of washing, properly so called. This is effected in various ways, such as by the *jigger*, the *inclined plane*, the *dolly-tub*, *et cetera*, all of which are so obvious in principle, and bear so much resemblance to similar apparatus already described in the

articles COPPER and GOLD, as to render a detailed description unnecessary. It may be stated, however, that in general much waste is occasioned in the English establishments in cleansing the ore, and the washing is not carried to the same degree of perfection as in other countries; doubtless from the circumstances that fuel in this country is plentiful and cheap, and labor is dear, while in Brittany and other localities the reverse is the case. In Cumberland the washing of the ore is usually let by the piece, and the men are paid according to its richness; thus, two shillings and sixpence is paid for cleansing fifteen hundred-weight of one kind, and for others, a sum ranging up to ten shillings, according to the quality of the ore.

THEORY OF LEAD SMELTING.—The smelting of lead ores with a view to the metals which they contain, demands no little amount of attention, to perform the operation in the most effective manner. The details of the process differ considerably according to the position of the works in relation to fuel, the nature of the ore, and its peculiar richness in silver, *et cetera*. So far as regards the reduction of the metallic lead, the principles of the various reactions may, however, be referred in most cases to the decomposition which takes place at a high temperature, by the mutual effect of an oxidised compound of lead and the sulphate, whereby the non-metallic elements are driven off, generally as sulphurous acid, and the metal is left. To bring about such a change it is customary to submit a portion of the galena to a preliminary roasting in contact with air, during which considerable quantities of sulphate of lead are produced by the oxidation of the sulphur and metal of the galena. This being done, the roasted and the crude materials are apportioned and heated in a furnace with due precautions, till the lead flows off, leaving a residue of the crudities of the ore, together with a portion of the unreduced substance. Much of the tact and knowledge of the smelter is shown in the manner in which the admixture is made, and in the subsequent application of the heat. And without knowing the reactions which take place, the operator can never be certain of success, but is subject to the risks and hazards arising from the different qualities of ore and imperfect roasting.

Indeed, the knowledge of the behavior of the galena under the influence of a high temperature, is the key to a comprehensive view of the whole business of lead smelting. When sulphide of lead—galena—is heated in a close vessel, out of contact with air, no change takes place beyond fusion, if the heat be sufficiently intense. This is not the case, however, if air be admitted, and allowed to flow over the fused mass; for then not only will the sulphur be oxidised, but a portion of the metal will be volatilized. Hence it is, that in operating upon lead ore, in particular kinds of furnaces, large quantities of the lead are driven off in vapor.

When the temperature applied is low, and the air freely circulates through the ore, the sulphide is converted into sulphate of lead, which resists a higher temperature, and is consequently more fixed. A mixture of sulphate of lead and of sulphide, affords upon the

application of heat sulphurous acid and metallic lead, which react upon one another, as represented in the formula:—

Resolved into

or

From this it may be seen, that by the action of the heat, one equivalent of the sulphate and one of the sulphide afford two equivalents of lead—that is, the whole of the metal which they contain—and two equivalents of sulphurous acid. By making the composition of the charge, from which the metal is to be eliquated, as near as possible to the above formula, there is no doubt but that the most perfect and economical decomposition will follow, and nothing will be left to desire beyond the regulation of the proper heat. It is not so, however, when the ratio between the sulphate and sulphide in the charge is altered, and more especially if the sulphate be in excess. Thus, if instead of an equal number of equivalents of the two ingredients, one of the sulphide and two of the sulphate be employed, the effects will be less advantageous; for in this case, only one equivalent of metal will be obtained, as the equation shows.—

A further increase of the amount of the oxidised compound would be productive of still less satisfactory results, and hence, if the ratio of the sulphate to the sulphide of lead be as three to one, no metal will be obtained, as shown by the formula:—

but instead, four equivalents of oxide of lead—Pb O—and four of sulphurous acid result. From these facts the obvious inference is drawn, that an excess of the well-roasted ore, which represents the sulphate of lead, must be avoided when compounding the charge. By employing a larger quantity of the galena representing the sulphide of lead, than is stated in the first of these formulæ, the consequences are not so bad as those just explained; for in this case, a portion of the sulphur, usually amounting to one-half, passes off as sulphurous acid, and the remainder is left united with the metal as a subsulphide of lead, which requires a much less amount of roasted ore for its reduction than the ordinary galena; neither does it require such a high temperature: and, owing to its entering into rapid fusion, it forms a layer upon the reduced metal, whereby the latter is preserved from the oxidising influence of the air.

Sulphide of lead is decomposed, without the intervention of an oxide of this metal, in a very perfect manner

by metallic iron, which takes up the sulphur from the lead, and forms therewith sulphide of iron:—

The heat required to effect this change is, however, much more elevated than that which answers for the preceding decompositions. An oxide of iron, such as results in one of the processes to which pyrites are subjected in the manufacture of sulphuric acid, would answer the purpose of the iron much better; for a lesser quantity of the material would suffice to reduce a large weight of the galena, and at a comparatively low degree of heat. In this case the change which would result is symbolized in the annexed equation:—

A double advantage may be derived from the adoption of this method of decomposing the galena, namely, the reproduction of iron pyrites, which may be utilized in the manufacture of sulphuric acid.

Of all these reactions the simplest in execution is that wherein metallic iron is employed, for only a mere heating is necessary to produce the lead. In large works, however, this is never resorted to, unless the mineral possesses such properties as necessitate the application of iron. That which is most general is the first-mentioned, in which a sulphate of the metal is produced, and this, mixed with galena, is subsequently acted upon by the heat to separate the metal. By a preliminary roasting the galena is converted into sulphate of lead, either in an open heap or in a roasting furnace. The method of heating the subsulphide of lead is frequently resorted to with advantage, as by it large quantities of metal are obtained, together with protosulphide of the metal which remains, and may be further operated upon.

THE FURNACE.—Three kinds of furnaces are used by lead smelters. In England and Wales the reverberatory form is exclusively employed, and no other affords more rapid results; the *Scotch Furnace* has been adopted at Alston Moors, and in some places on the Continent; and the high or tuyere furnace is employed where the ore is refractory or fuel is scarce.

The reverberatory furnace, called the cupola, is of very ancient origin, and has long been in vogue in North Wales, whence the models were brought to Derbyshire about the year 1747 by a company of Quakers. Long before this, the lead ore of Derbyshire and the North of England was smelted in very rude furnaces, called *boles*, the fire being urged by the natural force of the wind. For this reason the furnaces were always constructed on the Western side of an eminence. To these succeeded furnaces urged by bellows, similar to those of a smith's forge, and worked by water-power.

The form of the reverberatory is represented in plan, Fig. 320, and in elevated section, Fig. 321. Generally, the sole of the furnace, A, is eight feet in length by six in breadth, and is constructed of the fused slags

from the preceding operations, worked into the necessary form, during the time they are in a semi-fluid

Fig. 320.

state, by a strong iron rake. The shape of the sole is that of a shallow basin, in which the fluid metal collects at the deepest part, and is drawn off by a tap-hole shown in the section at B. By means of a solid bridge, E, of firebrick, the fire, D, is separated from the hearth; it is usually about two feet thick, and about one foot in height, leaving from fourteen to eighteen inches space between it and the arch for the flame to pass over. As shown in the drawing, the arch, C, gradually declines towards the further extremity of the hearth, from which it is elevated only six inches, the height from the deepest part of the depression in the bed being only two feet. At the extremity of the furnace, opposite the fire, there are sometimes two openings, separated by a triangular prism of firestone, which lead to a flue, F, a foot and a half wide and ten feet long, which is recurved towards the top, and runs into an upright chimney fifty-five feet high. This flue, for a short distance from the furnace, is covered with flat tiles closely jointed in fireclay, but which may nevertheless be easily removed. Such an arrangement is necessary in order that the *lead fumes*, which at a high temperature are freely sublimed, may be cleared away and the freedom of the draught insured. One of the sides of this furnace is called the *laborer's side*, being that from which the fire is supplied with fuel through the door, G; on the

Fig. 321

same side are three other openings, H H H, which are closed by sliding plates, and vary in area from six inches square to about eight inches by twelve. When

necessary, the charge is stirred through these openings, and they are also useful for admitting air when the process of roasting requires it. Opposite is the *working side*, in which are five apertures; three corresponding with those on the other side, and similarly secured, and the other two, below them, used for running off the metal and scoria. Towards these last the bed of the furnace inclines in such a way, that the part which is opposite is nearly up to the aperture H, whilst at the tap-hole it is eighteen inches below H, on the same level. The lead flows into a cast-iron pan, I, set in a niche a little under the side. There is in the middle of the arch an opening, to which is fitted an iron hopper, where a charge of ore is deposited whilst that in the furnace is being worked; and when the latter is drawn off, the material in the hopper is let into the furnace, by drawing a slide.

The preceding is the kind of furnace employed at Grassington in Yorkshire, and in which the roasting and smelting are conducted. In those localities where the two operations are conducted separately, as at

Fig. 322.

Redruth and other places in Cornwall, the roasting furnace employed is that represented in Fig. 322. A is the fire, and B the fire-bridge; C C, separate ducts by which the smoke passes off to the chimney; E E, working doors, which allow the workmen to spread and stir up the charge of ore as required; and F F, smaller apertures serving the same end, and admitting air for the combustion of the sulphur of the mineral. The sole of the furnace is a cast-iron plate, upon which layers of firebrick are accurately fixed together, the whole being supported upon pillars, as shown in the drawing. Besides the apertures already mentioned, there are others, G, generally at the end opposite to the fire, through which it is rabbled at intervals. The size of this furnace is smaller than that in which both the roasting and smelting of the ore are performed.

At the works near Holywell, North Wales, the furnaces employed are of that kind in which the roasting and smelting are performed successively; they are very similar in form to that already described, only that there is no opening for running off the slags. The hearth is

hollowed out below the middle door of the furnace, the back and ends being made to slope towards this part. Twenty-four inches is the ordinary depth from the bottom of this basin to the sill of the door; but it varies a little according to the kind of ore operated upon. In the other details of the hearth and arch these furnaces are similar to those already mentioned. In this locality, however, the flues from all the furnaces enter one main, which leads to a chimney disposed as represented in Fig. 323.

Here the furnaces are shown as at *a a a*, and the separate flues, *b b*, opening into a main channel, *c c*, five

Fig. 323.

feet deep by two and a half wide. Another one, *d*, six feet deep by three in width, opens from the latter into a circular chamber, *e*, fifteen feet in diameter, wherein, as well as in the conduits leading to it, the *lead-ashes* volatilized from the furnaces are intercepted. From *e* the smoke is conducted by a similar flue, *f*, which enlarges as it approaches the chimney, and where it is joined by the flue, *g*, from another department of the furnaces, to a depth of seven feet and a breadth of five. The chimney has a diameter of thirty feet at the base, tapering to the top, where it measures twelve, including the thickness of the walls; its height is one hundred feet; but as it stands upon an adjoining hill, which is about sixty feet above the level of the furnaces, the total height of the flue may be said to be about one hundred and sixty feet. Such an arrangement is necessary, in order to draw off, out of the range of the inhabitants, animals, and vegetation of the neighborhood, the enormous quantity of sulphurous acid which is evolved from the thousands of tons of ore worked annually.

In many parts of England, more especially in the counties of Durham, Cumberland, and Northumberland, the smelting of the lead ores is conducted in the *Scotch furnace*, or *ore hearth*. It is shown in Fig. 324, and consists of a rectangular cavity of masonry, *a b w*, twenty-four inches in length by a breadth of twelve, and a depth varying from twenty-two to twenty-four inches, the whole inclosed in an arched hood, *p*. A considerable portion of the hood, on the near side, is removed to show the interior arrangements. The cavity is entirely lined with cast-iron, the bottom portion, *b w*, being one entire piece, having a ledge five inches in height and two in thickness surrounding every part of it, except on the side facing the *workstone*, *A*, placed at one end of the rectangular construction. The ledge upon the side, *B w*, is removed to show

the interior of the cavity. The workstone, *A*, is likewise surrounded by a ledge, *b*, on all sides except that near the hearth, and which either rests on the ledge surrounding the hearth bottom, or is united to it and forms part of the casting. In either case it is fixed at an incline of about six inches. On the back edge of the furnace bottom is placed a prism of cast-iron, *C D*, called a *backstone*, six and a half inches square in section, and twenty-eight in length, on which rests the nozzle of the tuyere. Above this is placed another cast-iron prism of the same length, and eight inches in height, which is known as the *pipestone*; it has a cavity in its centre for the introduction of the tuyere, and projects about two inches over the hearth. A third stone, *E H*, is fitted on the latter, and completes this side of the furnace, making its total height from the sole-plate twenty-five and a half inches. Two prismatic castings, called *bearers*, are placed along the lateral sides, twenty-six inches long and five square, and projecting slightly over the edge of the workstone as well as of the posterior backstone; these contribute effectually to give solidity and fixity to the parts. These bearers support, through the intervention of several ranges of firebricks, a piece of cast-iron of the same dimensions as the lowest backstone, and which is called the *forestone*. This piece is in contact at each of its extremities with another mass of cast-iron, six inches cube, and supported on the brickwork; this is called the *keystone*. Finally, the spaces left between these keystones, at either side, are filled up with other blocks of castings similar to the latter.

When the workstone, *A*, is not connected with the sole-plate, *B w*, the space between them is filled up with a cement formed from ground bone-ash and galena, thoroughly mixed and pressed firmly into it. Before the workstone, and set in masonry inclosed in a cast-iron jacket, is the lead-pot, *G*, into which the freed metal flows through the channel, *a a*, which is sunk beneath the surface of the plate. It is placed close to the furnace, in order to prevent the escape of lead

Fig. 324.

fumes as much as possible. This is more completely effected by the hood, *p*, in which is a flue communicating with a chimney, and in which is left a small door for the introduction of the ore and fuel. The movable iron plate, *K*, in front admits of being raised or depressed at pleasure, whenever the draught requires

it; and the blast, which is forced through the tuyere, is regulated by a valve placed in a pipe, which is approached by the door-way, L, left open for this purpose. Heavy iron bands are employed for binding the brick-work more firmly, as shown in the figure.

Smelting in Reverberatory Furnaces.—It is seldom that any other kind of furnace is adopted for lead smelting in England, besides those above-mentioned. The routine of working which the English smelter pursues when the reverberatory furnace is employed, will now be described.

The fact has been already stated, that the process of smelting is modified according to the nature of the ore. Generally speaking, the average richness of the English ores of lead is about seventy-five per cent. of metal; but in many specimens there is found not more than twenty per cent.; and, in fact, ore is often met with varying between these extremes. The remaining constituents are composed of sulphur, the stony matter of the rock in which the *lode* is found, *et cetera*, and which consists, for the most, of sulphate of baryta, carbonate of lime, silicates, and sometimes—as in some of the ores at Holywell—carbonate of zinc, and the like. In order to produce a fusible compound, which will melt at as low a temperature as possible, a judicious admixture of two, three, or more kinds of ore is made, according to the nature of the non-metallic impurities; and it is often found necessary to have recourse to fluxes. When, however, the gangue is of such a nature as to melt readily, such additions are unnecessary. A properly-conducted analysis of the ore will always enable the experienced manager to judge of the additions that are best calculated to favor the separation of the impurities.

In the lead works in the neighborhood of Alston Moor, as well as in those of Derbyshire, the charge is composed sometimes of as many as seven varieties of ore, and weighs only sixteen hundreds of one hundred and twenty pounds each; but in the very extensive works belonging to Messrs. WALKER, PARKER, and Company, the charge is twenty-one hundreds, and is rarely composed of more than two or three kinds of ore. In the latter works this weight of ore is put into the hopper; and, as soon as the furnace is brought to a dull red-heat, or after drawing out the slags from the last charge—if the furnace has been working already—the slide in the neck of the truncated cone is withdrawn, and the ore is allowed to precipitate itself upon the bed of the furnace, where it is spread out into an even layer, through the furnace doors at the back. No effort is made at this period to urge the heat; it is rather allowed to sink; and only a few spadefuls of coals are thrown upon the grate at intervals, to maintain the heat at the moderate standard required. After spreading out the ore, all the working doors, as well as the outlets for running off the slags and metal, are closed, and the damper is lowered. As soon as the ore becomes heated, and the sulphur begins to escape as sulphurous acid, if any rich slags remain from a preceding operation, they may be thrown into the furnace at the opposite doors furthest from the fire, and spread out like the ore. Air enters the furnace through a rectangular slit over the tap-hole; this is left open all the time that the roasting continues. After the charge of ore attains a

dull red heat, and the sulphur begins to burn off, the heat produced is nearly sufficient to carry on the roasting, independently of the fire in the grate; still, this is maintained, but only feebly. At the expiration of a quarter of an hour, the ore is well turned over with the paddles, so as to present a fresh surface, and to cause the evolution of a fresh quantity of the sulphur. One hour and three quarters are devoted to this part of the operation, the intervals between the rabbling of the charge being occupied in casting the lead from a previous charge into pigs. In the course of the roasting of the ore, some metal is produced from the reaction of the rich slags thrown in at the upper door upon a portion of the galena; this metal is drawn off at the proper time. Coal is added generally to effect the reduction, and rabbled with the molten mass some short time previous to the metal being drawn off. Whilst the smelter is tapping off the reduced lead, and throwing the scoria—which floats upon the bath—back upon the furnace, the assistants are stirring up the ore with their paddles. The slags from the bath of metal, as well as the rich ones from the previous charge, being thus partly smelted, and the ore roasted or oxidised to a certain extent, all the doors of the furnace are opened, and the ore is thoroughly turned over towards that side on which they work.

At this period the vapors of sulphurous acid have considerably diminished, and the temperature of the interior of the furnace becomes lower. The lead, which before this rabbling and cooling was beginning to ooze out, is checked. Some coal is now thrown upon the fire; the damper is slightly raised to increase the draught—the doors of the furnace being all closed during the time that the firing is taking effect. This is recognized as the *second stage*, or *firing*; the first being the *roasting* of the ore. In about half an hour the furnace assumes a red heat, and the material contained in it begins to flow down the incline of the sole towards the basin. The doors at this juncture are opened, and the smelting matters pushed by the smelter to the front of the sole, near the bridge, where they are spread out by his assistant from the opposite side. A little quicklime is now thrown upon the bath of metal through the middle door, and the ore and melting matter is worked through the doors at the back for a quarter of an hour; then spread out upon the sole. Meanwhile the smelter, with a long rake or paddle, forces the slags from the surface of the metallic bath towards the bridge.

A little respite is now given to the operation, the doors being left open for a short period; during which the lead remains in repose, and the metal, which was forced back with the slag, descends again into the basin. It is assumed that the cooling of the furnace at intervals, in this manner, not only facilitates the separation of the gangue from the metal, but shortens the time of smelting in every way. Some fuel is thrown upon the grate, to maintain a moderate heat; and the workmen resume their rakes, and turn over the slags and ore. When this is done the doors are closed, and the grate is charged with the third firing; the damper is entirely drawn, and the furnace is left to itself for three quarters of an hour. This *third firing* is given three hours to three and a half

after the charging; and at the end of the fourth hour the doors are again thrown open, and the charge stirred by the assistant opposite to the smelter's side, for the purpose of facilitating the flow of the metal into the basin of the hearth. The slags are once more pushed from the surface of the bath of metal by the smelter, and spread with the ore by the assistant. If the galena should happen to be silicious, a portion of the oxide of lead is taken up by the silica during the preceding period, and flows down upon the reduced matter in a matt. To decompose this a quantity of quicklime is thrown in from the front, agitated with the mass slightly; then the doors are once more secured, and the fire is replenished.

At this period the practice is to throw a little slack into the furnace, with the view of assisting in the reduction of the oxidised compounds of lead which may still exist, as well as to prevent the oxidation of the metal. This is the period of the *fourth* firing, and lasts forty minutes; so that its effect takes place in about four hours forty minutes from the hour of charging. Now the doors are opened, the smelter pierces the tap-hole, and allows the reduced metal to flow out into the basin sunk in the floor outside. Quicklime is thrown upon the slags which remain, in order to dry them; he then pushes them towards the back, whence the assistant draws them out at the back doors.

Thus the smelting of a charge of ore of twenty hundred, at the Dee Bank Works, usually occupies a period of four hours and a half; but when the slags, instead of being dried up, are melted, a further firing is necessary, and the operation occupies a longer time. Generally speaking, the furnace is ready for the reception of another charge in six hours; so that, in the twenty-four hours, there are four charges worked off by every furnace. The week's work extends to twenty-two charges, generally, although the standard is limited to sixteen. Unless the ores are very refractory, the quantity of lime required for each charge amounts to one hundredweight; but some ores are worked which take as much as two hundredweight of this agent. The lead from the charge of twenty hundredweight of ore averages from fifteen to sixteen hundredweight. The richer slags which form on the bath of metal are worked with the succeeding charge, in the manner described; but the remainder are smelted—by a process to be described further on—in *slag-hearths*, built on the German principle. It is often found necessary, when very fusible slags are produced in the furnace, or the metal becomes more or less oxidised, to employ billets of wood, in the same way as the *polling* is effected in the refining of copper; only that, in the case of lead, it is not performed within the furnace, but in the pan without, whilst the lead is hot. The quantity of coal employed for the smelting of each charge weighs, on an average, about half a ton.

In the Grassington works, Yorkshire, the ore is composed of galena, mixed with carbonate of lead, and a gangue of carbonate of lime and sulphate of baryta. Here, as at Holywell, the charge is generally twenty hundreds. The period of roasting extends from three to three and a half hours, and the melting for metal succeeds almost in the manner described. Quicklime,

mixed with slack, is used to dry the slags, which are spread upon the sole of the furnace; and the melting for metal, and drying of the slags, are repeated three times in succession. Fluoride of calcium—fluor spar—is sometimes used as a flux, and the bath of metal in the basin of the furnace is always kept covered with lime. Seven to eight hours are occupied by the working of the charge, and the metal obtained weighs from sixty-one to seventy-two per cent of the ore. Owing to the materials being less refractory, the consumption of coals here is somewhat less than at Holywell.

At Lea, in the neighborhood of Alston Moor, the ores smelted are, for the most part, of two kinds—namely, an almost pure galena, and another ore of lead, which has the annexed composition:—

	Centesimally.
Sulphide of lead,	55.00
Carbonate of lead,	23.00
Sulphate of baryta,	19.00
Clay,	3.00
	100.00

In the reverberatories at Pezay, in France, fir-wood is used for fuel, of which about four stères are required for smelting each charge of one thousand two hundred and fifty kilogrammes, or twenty-five hundredweight of the ore, the richness of which averages about seventy-six per cent. of metal.

In all the works mentioned, and in fact wherever the reverberatory furnace is employed, the principles of the operation are explained thus:—During the first stages, a greater or less quantity of sulphate of lead mixed with oxide is produced; the several rabblings which are given to the charge during the period that the temperature is retained at a low degree, tend to increase these substances, and to mix them more intimately with the ore, so that when the firing for the production of metal is given, the reaction,

as formerly described, may take place. The partial cooling of the furnace after the second firing, is supposed to forward the same ends, inasmuch as the temperature which, if continued, would melt the materials and considerably retard oxidation, is slackened, and after the proper interval, the charge bears to be stirred as when in its most friable state.

Smelting in Blast Furnaces.—The use of the blast furnace involves the necessity of a somewhat different treatment. The *Scotch furnace* or *ore-hearth*, described at page 465, may be taken as the type of this kind of furnace when adapted to the smelting of lead ores.

Generally very rich ores are operated upon where the Scotch furnace is employed; and these are subjected before smelting to a preliminary roasting in a furnace of the reverberatory class.

From nine to eleven hundredweight of ore constitute a charge, and two and a half to three hours are required to effect their calcination; so that about nine charges are drawn during twenty-four hours. The heat of this furnace is kept purposely lower than the melting point of the galena, but sufficiently high to effect combustion of the sulphur with the oxygen, whereby it is converted partly into sulphurous and partly into sul-

phuric acid. Evidence of these changes is observed in the heavy dense fumes which fill the furnace and escape into the chimney. When a portion of the charge softens and becomes somewhat agglutinated, a fresh surface is presented to the flame by rabbling, and moving the hotter material to a colder part of the hearth. When slime ores are operated upon, the temperature is kept such as to render the mass somewhat pasty, in order to prevent the loss which the draught would occasion if the ore retained its friable quality. The roasting of the charge being effected, the material is drawn out by the door, and falls into a tank or well of water, whence it is subsequently raised and dried before submitting it to the operation of smelting. In this state it is a compound of oxide of lead, sulphate, and subsulphate, with undecomposed sulphide. Roasting the mineral in heaps was a practice once common enough, but is now obsolete, at least in England and the neighboring countries.

The roasted ore and coal are introduced into the smelting furnace after the latter has been heated by a preliminary firing, and the blast is thrown in either by a good condensing engine or by a fan worked by steam. To heat the furnace, the practice in the English smelting districts is to fill the cavity with peat, cut into the usual prismatic form, taking care that those towards the front are regularly placed in layers, one above another. A few ignited coals are placed immediately before the tuyere or nozzle, by which the blast enters, and the air is forced in gently, in order to ignite the mass. Some small coal is also thrown on the peat, when it is thought that the heat produced by the peat alone is insufficient to bring the furnace to the proper temperature. When the whole of the fuel is ignited, and the furnace has acquired sufficient heat, the *browse* from a preceding charge, if there be any, is thrown upon the ignited mass, and the blast continued as before. In a short time the portion of browse that remained on the hearth, together with that added, softens, and is drawn out upon the workstone by means of a large rake called a *goveloch*. Here the experienced workman is enabled to distinguish and separate the poor slag from the richer material by the color; the former, which has a shining grey appearance, is thrown with the spade in a heap to the right of the operator, and the latter is set aside to be again returned to the furnace. If the browse retains much slags, or, owing to its being very fusible, comes out in a pasty state, some quicklime is added, which, by uniting with the silica, causes the material to become more refractory, and at the same time disposes the lead compounds present, to yield up the metal with greater facility in the subsequent operation. This base is employed also to effect the opposite change of rendering a refractory slag less so, but in much smaller quantity than when it is used, as the saying is, to *dry* the mass. The grey slag, which is thrown to the right, and which contains from a fifteenth to a tenth of its weight of lead, is subsequently smelted in what is called the *slag hearth*, while the richer material, consisting of semi-reduced ore, mixed with fragments of coke and clinkers, and termed *browse*, as already mentioned, is mixed with some slack, and reintroduced into the furnace. A brick of peat is placed

before the nozzle of the blast-pipe, in order to spread the current, and the whole is heated for about a quarter of an hour, at the end of which the materials are raked out on the working-stone, where some lead is sweated from the mass, and a portion of grey slag separated. Some small coal and a greater or less quantity of lime are again thrown into the furnace, a square of peat is placed before the venthole, the browse is reintroduced together with a small quantity of fresh ore, and the furnace urged for fifteen minutes longer, when the material is drawn out as before, and the grey slags separated, as well as the portion of metal which becomes reduced. Thus every quarter of an hour the *browse* is returned into the furnace, with the necessary addition of fuel and fresh ore; and, at the same interval, some lead is separated from the mass on the workstone, and flows into the receiving-pot. The operation is continued uninterruptedly for fourteen or fifteen hours—termed the *shift*—in which time from one to two tons of metal are obtained. The furnace is then allowed to cool for some hours, before another shift is commenced. Lead prepared in this way is esteemed for its purity, which arises from the comparatively low degree of heat applied in its preparation, being inadequate to the reduction of any other metals excepting the lead and silver.

At Pezay, in France, the operations conducted in this kind of furnace are much the same as have just been described; but there is a division of the work, the first part being distinguished as the *fluxing* or *melting*, and the second as the *sweating* or *eliquating*.

The ore which is occasionally treated in the Scotch furnace, when it contains much carbonate of lead, is not subjected to a previous roasting, but at once submitted to the smelting operations described.

The Slag-Hearth.—In England, as well as at Pezay and other places, the slags from the reduction by the ore hearth, and also from the reverberatories containing a variable amount of metal, are reduced in what is called the *slag hearth* in the English establishments, and *fourneau a manche* by the French.

This furnace is seen in section in Figs. 325 and 326, in which A shows the cast-iron plate forming

Fig. 325.

the base of the furnace; B, the pot or basin in which the lead is collected, and which is filled with cinders, *et cetera*; C is the tank containing water, and used to cool the slags which flow into it, after passing over the basin, B, and depositing therein the lead; and D shows a pipe which supplies the tank with cold

water. The form of the furnace is generally that of a rectangular prism, twenty-six inches in length, twenty-two in breadth, and thirty-three in height. The plate of iron, A, forming the bottom, is slightly inclined to the front, and on each side of it are bearers, as in the ore

Fig. 326.

hearth, for supporting the fire hearth, which consists of two stout plates of cast-iron about twenty-six inches long by twelve inches broad. By this arrangement a space of about five inches is left between these plates and the bottom of the furnace, and an additional height of two and a half inches is gained by placing upon them a row of firebricks. In every other respect this furnace differs but little from the ore hearth, only that the temperature is much higher in it than in the latter. From the basin, B, the accumulated metal flows by a pipe into the metal pot, E, whence it is cast into pigs.

At the Dee-Bank Works of Messrs. WALKER, PARKER, and Company, to which allusion has already been made, there are eight of these in operation for working off the slags from the reverberatory smelting furnaces. Peat is used to heat the furnaces when first set in operation; this is lighted in the usual way and the blast set working. The peat is surmounted by a layer of coke, and when the temperature rises to the melting intensity, a layer of the slags, or scoria, is introduced. After this the temperature is kept up without intermission, and the furnace is charged with successive layers of coke and slags as the matter sinks in the furnace. The materials enter into fusion ultimately; but before this change is effected, there is a deoxidation of the sulphate of lead in the higher part of the furnace, and a subsulphate or sulphide produced instead, which, acting upon the undecomposed sulphate, liberates the lead of both, the sulphurous products being volatilized. The oxide of lead which might also be produced by the reaction of the excess of lime present, is likewise reduced by the charcoal to the metallic state. By virtue of its gravity, the lead separated descends through the molten mass. The metal obtained in this way is never large in quantity, and is accounted of inferior quality, owing to the great heat at which it is produced, reducing other matters, such as iron, *et cetera*, and which are alloyed with the lead.

Smelting Silicious Galenas.—In many Continental localities where the galena is very silicious, a process of smelting is followed, different in its nature and characteristics from that which has been detailed, as well with reference to the reverberatories, as to the high furnaces. For the difference of treatment, a direct necessity exists, inasmuch as were such silicious galenas worked by the *method of reaction*, that is, roasted with the view of generating a quantity

of sulphate of lead which might be made to react upon the unaffected sulphide, so as to precipitate the metal from both, a very serious loss would be incurred; because instead of inducing such a change by the fusing temperature finally applied to the ore, a combination of the oxide of lead and silica arises, and the silicate so produced, besides being difficultly decomposed, has no action upon the sulphide and sulphate of the metal, and, consequently, a large quantity of metal would pass off unreclaimed. The process adopted is founded upon the reduction of the sulphide of lead by metallic iron, whereby the negative element is transferred to the latter metal, and metallic lead separated, as shown in the equation:—

As is evident, the decomposition of the galena is perfect, and takes place in equivalent proportions, so that, by the use of twenty-eight parts of iron—one equivalent—one hundred and four parts of lead—also its equivalent—is produced.

At Clausthal, a quantity of ground and washed ore is taken and mixed with various other products, resulting from foregoing operations, together with a proportionate quantity of granulated cast-iron, and the scoria which are detached from this metal when working it under the hammer, *et cetera*, and the whole is fused in a small high or blast furnace, such as is represented in the annexed engravings. Figs. 327 and 328 show a front elevation and section, and Figs. 329 and 330 a

Fig. 327.

Fig. 328.

side elevated section and plan. The shaft, A B, is about twenty to twenty-three feet high, and about three and a quarter in breadth at the widest part. Usually the shaft interiorly presents the appearance of two inverted crucibles, the lower one, or B, contracting towards the bottom, and the upper, or A, towards the top. At the

base of the shaft is found the crucible, the base of which is formed of two grit-stones placed so as to form a channel at their junction. Upon these stones a mixture of clay and charcoal is firmly pressed,

Fig. 329.

so as to face the whole up to the furnace part, leaving a cavity in the middle, as indicated by C and D in the figures. An aperture connecting the crucible, D, with a second crucible, E, Fig. 330,

by means of a gutter or pipe, permits the fluid matters in the former to run into the latter. The blast is introduced by two tuyeres placed in the face opposite the tryp. The mineral is charged on the tuyere side, and the fuel on that which

is opposed to the blast, and as the heat advances, the scoriæ which attach themselves to the nozzle are quickly cooled, and form an elongation of the latter of about

Fig. 330.

three inches, which enters into the furnace. This incrustation, called the *nose of the tuyere*, is of importance, inasmuch as it conveys the blast to the fuel, and all the oxygen being

combined in this, oxidation of any of the mineral constituents is prevented. Indeed, the proper management of the *nose* requires all the care of the smelter, as upon it much of the success of the reduction depends. The superior part of the furnace is kept at as low a heat as possible, in order to prevent the volatilization of the sulphide of lead. But, in addition to this precaution, the volatile product traverses from the mouth of the furnace, by a number of chambers, before it enters the chimney, so as to intercept the *lead ashes* which volatilize. These chambers are emptied periodically, and the product smelted with others in the usual way. In working this furnace the melted matters flow out continually into the crucible, D, and when full the connection with E is opened, when the contents are transferred to the latter, the metal forming the under part, and the slags the superior. When the aperture becomes closed by the cooling and solidification of the scoria, the obstruction, is removed by an iron bar and hook. The scoria which covers the metal in the outer crucible, is composed of a subsulphide of lead, sulphate of lead, particles of iron, and other substances. It is called the *first lead matt*. After being removed by an iron hook from the bath, the metal is poured through a metal cullender or sieve, to separate fragments of slag, and then cast into pigs.

If the scoriæ be poor in lead, they are rejected, but the richer products are retained to be worked up with a further quantity of roasted ore; but sometimes they are collected till there is a sufficient quantity to be reduced separately.

The original mixture is composed generally of—

- 34 parts of mineral, containing about twenty-four of pure galena.
- 4 to 5 parts of the debris of the cupelling furnace, and impregnated with litharge.
- 1 part of the first litharge—called *abstrichs*—formed in the process of cupellation.
- 39 parts of scoria obtained from the first fusion of the mineral, *et cetera*.
- 4½ parts of granulated iron.

REGNAULT states, that this mixture yields nineteen parts of metal, and seven or eight parts of first matt, containing two and a half parts of metal.

At Tarnowitz in Upper Silesia, the rich mineral obtained there, and containing about eighty per cent. of lead, is treated in a blast furnace like the last-mentioned, with about twelve per cent. of old iron or shot, and as much of the rich matt from the preceding as is thought necessary, together with thirty-six per cent. of the scoria from the same operation, to confer fusibility. About fourteen per cent. of coke are consumed, and the products are sixty per cent. of lead, and twenty-four of matt rich in lead. Most of the scoriæ are rejected. The campaign, or smelting period, continues six days uninterruptedly, in which time thirty tons or more are smelted on an average. The poorer ores, yielding only fifty per cent. of lead are smelted in a high-blast furnace.

In this case the additional matters are, for a hundred of the ore—

- 32 parts of matt from the smelting of rich mineral,
- 12 „ debris of cupelling furnaces, *et cetera*,
- 10 „ scales from the iron forges, and
- 24 „ scoria from the refining.

Forty-three per cent. of coke are used, and the produce of metal amounts to about forty per cent. of the ore operated upon. Each smelting campaign lasts a week, and the produce during this period averages from twenty to twenty-two hundreds of metal.

Generally speaking, those minerals which are rich in silver, and contain large amounts of gangue of a silicious nature, when subjected to the preceding treatment, give a matt which still retains a portion of the noble metal, and on that account is reserved to go through a second fusion.

PURIFICATION OF LEAD.—In almost every case, the lead which is obtained from galena and other ores contains more or less silver, varying, in the English ores, from twelve or more ounces per ton of lead smelted to two ounces or less. In other varieties of lead ores, such as those worked in many establishments on the Continent, the yield is greater, averaging as much as nine per cent. of the lead. When the precious metal is in so large a proportion, the lead is termed workable metal, that is, in a fit state to be cupelled for the silver; but as most of the lead produced in Great Britain was found to yield only quantities averaging, for the richest, ten ounces per ton or thereabouts, and often as low as two, the trouble of recovering this was thought

to be more expensive than the gain in silver, and consequently it was left in the lead. A very simple and unfailing method, however, is now pursued, founded upon a property of the alloy of lead and silver, whereby such lead as contains only about two ounces of silver to the ton of metal can be economically worked for the recovery of the silver. To this process reference will be made presently. Besides silver, there are other impurities found in much of the lead produced on the Continent—more especially in such as is reduced from ores containing the tersulphide of antimony, blende, and the like—owing to an alloy of these metals with the lead being formed. Of course these metals destroy in a great measure the characteristic properties of the lead; so much so, that sometimes it cannot be employed, in many of its applications, till it has been submitted to a process of purification; and when the impurities alluded to exist only in very small quantities, the quality of the metal is so deteriorated, that it will not resist the air or liquids, or work under the roller with satisfaction. Such impurities are occasionally detected in small quantities in some of the English lead; seldom arising from the native ores, however, but rather from parcels of foreign imported mineral. It will be evident that the latter impregnations are much more injurious than silver; for, notwithstanding that this metal renders the lead hard under the roller, it enables it to resist the action of the air better; whereas the other impurities mentioned destroy, to a great degree, the natural power of the lead to resist the air. Traces of iron are frequently found in the lead, when ferruginous gangue or pyrites is associated with the ore; the iron is never removed, however, by any special process, owing to the amount being too minute; nevertheless, the quantity, even though it be only a small decimal part of a per cent., is found to be highly injurious in the manufacture of red lead and carbonate of lead from the metal.

The method adopted for removing the antimony, tin, copper, zinc, and other foreign matters, is often tedious and expensive. It is founded upon the oxidation of those metals, and the separation of the dross of mixed oxides from the lead. To effect this, the smelted metal is re-melted in a reverberatory furnace, through which a copious draught is instituted, and allowed to remain in this state, the scum of oxide being removed from time to time till the most part of the easily oxidised impurities are separated.

To purify the metal, a variable period is required, dependent upon the proportion of the impurities present; hence it happens that whilst some kinds are sufficiently februated in twelve hours or thereabouts, other kinds require a prolonged treatment of several weeks. The dross is a mixture of the oxides of the metals present as impurities, and of lead; and from the color, when drawn out, an opinion is formed as to the extent of the purification. In addition to this, however, the refiner takes out a sample in the ladle, and pours it into a small mould; and, as it cools, he observes the change on the surface, and concludes accordingly. When the impurities are nearly removed, the surface of the assay assumes a peculiar flaky crystalline appearance,; and as soon as this is recognized,

the bath is cleaned from the dross; and the metal, retaining the whole of the silver originally present, is allowed to flow out into the pot, from which it is afterwards ladled into the moulds.

If this lead, thus deprived of the brittle and easily oxidised metals, be sufficiently rich in silver, it is submitted to a process of cupellation in a furnace similar to that represented in the annexed drawings—Figs. 331 and 332—which represent it in plan and section. In these A is the fire; B, the bridge; C, the cupel, which is movable, and composed of a sash or frame of iron bound by a rim of the same, presenting at the under part four transverse bars on the plan of that described at page 284—Fig. 229. The refractory materials, consisting of bone-ashes and very fine *cinders*, are placed on, and well beaten together. After

Fig. 331.

Fig. 332.

the whole is dried, it is inserted in the furnace as represented. EE are openings, either for introducing the pigs of rich metal or the melted alloy into the cupel; FF, means for forcing the blast; but in large works, where several refining furnaces are in operation, the air is urged upon the metal by means of a fan, driven by steam-power, and connecting pipes. The oxide of lead or litharge, produced in the course of the operation, falls into a receptacle, DD, beneath the cupel, and is periodically removed.

The furnace which is in use at Clausthal in the Hartz, is shown in Figs. 333 and 334, next page. Fig. 333 is a front elevation; Fig. 334, a plan on a level with the fire-bridge and tuyeres. A glance will be sufficient to show that this is a kind of reverberatory furnace, the bed of which is circular, and hollowed in the middle a little more than ordinary. The fire-grate, F, is shown at the side, with the draught and ash-oles, E. aa, are the apertures through which the air is blown into the furnace for the oxidation of the lead, which is introduced at the opening, F, in the form of discs; the lead,

thus deprived of its metallic characters, is emitted as litharge in the fused state through the opening, O, and falls upon the floor of the refinery, or into pots. A riveted plate-iron dome covers the sole of the fur-

Fig. 333.

nace; it is furnished with tackle, as shown in the drawing, by which it can be raised at pleasure. Much attention is given to the formation of the sole of the furnace. The first bed is composed of scoria, well beaten together, and hollowed as a sphere; and upon this a similarly-shaped one, of bricks placed closely together, is formed; and a third overlays the latter. It is constructed of *marl*, and beaten down firmly; but in the most cases, it requires renewal at every fresh charge;

Fig. 334.

the old material, which had become saturated with litharge, being employed afterwards with the matt and mineral in the smelting operations, as already detailed.

The furnace being in order, the charge of metal, amounting to one hundred and sixty quintals, is introduced, and the fire lighted; in a short time the lead begins to flow, and, as soon as the whole has melted, the blast of air through the tuyeres is forced upon the bath. The melted lead under this influence rapidly oxidises, and becomes covered with a blackish coating of oxide of lead, mixed with other impurities, and which, when removed, constitutes what is termed the *abstrichs*. This coating of oxide does not fuse,

but forms a solid covering, which would impede the oxidation of the lead, unless removed. Some charcoal powder is thrown in upon the metal from time to time; and, by the aid of a bar of wood, fixed crosswise upon the end of a bar of iron, the workman draws the *abstrichs* towards the door, O, through which they fall upon the floor of the refinery. After the removal of these matters, the blast is kept up, and fusible litharge begins to appear, and flows out at the aperture before-mentioned; the first portions, however, are very impure, owing to other foreign matters existing with the lead, and are consequently retained, to be *revivified* in the reverberatory or blast-furnace. After a while the product assumes a better color, indicative of its being purer; and, when it has appeared of the proper shade, it is collected for marketable or commercial litharge, and sold as such. When this happens, the blast is urged to effect the removal of the lead as quickly as possible, and the force of the stream of air kept up, till the entire of this metal is removed, and a disc of metallic silver remains.

The proper period for arresting the oxidation of the lead by the blast, is indicated by what is termed the *brightening* of the assay. Whilst the oxidation proceeds, the appearance of the metallic bath is much more luminous than the walls of the furnace; this arises from its temperature being more elevated, for not only does the bath acquire its heat from the fire, but also from the oxidising material, which develops much caloric. As soon, however, as the lead is removed, or nearly so, the temperature of the metallic residue falls to the mean degree of the furnace, and instead of remaining very brilliant, as it was before, it appears tarnished. On the other hand, when the last portions of lead become oxidised, very little remains upon the surface of the bath besides a pellicle of melted litharge, which diminishes rapidly, and presents in succession all the rays of the prism, and, finally, is torn asunder when the surface of the unoxidisable metal makes its appearance. It is this rapid succession of optical phenomena to which the above epithet of brightening is applied.

As soon as this appearance of the bath is observed, the workman throws some hot water on the surface of the disc of metal remaining, and after that some cold water, both of which rapidly reduce the temperature so much as to enable him to remove the silver. This residue is not absolutely pure, however, but contains from one-twelfth to one-sixteenth of its weight of lead, which is removed from it afterwards in the *refining* process, which will be described under *SILVER*. The hundred and sixty quintals of lead obtained from the *schlich* at Clausthal afford quantities varying from three hundred and ninety to four hundred and fifty ounces, according as the metal is obtained from the crude *schlich* or roasted matt, which is generally the richer. Thirty hours are occupied in cupelling the charge. The litharge which is produced towards the close of the operation contains a notable amount of silver, and on this account it is separated from the rest with the view of afterwards recovering the precious metal.

The *abstrichs*, cupel bottoms, and rich slags are afterwards passed through a blast furnace, whilst the

yellow and red litharge find their way, after being finely ground or reduced to powder, into the market. Sometimes, however, the better quality of litharge is reduced. This depends on the demand and the relative value of the metal and the litharge. Generally the lead produced from the fine litharges commands a better price, owing to its being very pure. Abstrichs and the first litharge that is produced in the cupellation are frequently smelted by themselves, especially when they are of an antimonial nature; and the impure lead thus produced is sold at a lower figure for the manufacture of shot.

Pattison's Process.—It will be evident that the oxidation and reduction of lead, when it contains only the one-thousandth of its weight of silver, would be unremunerative if this quantity were to be recovered by the method just described; and much less remunerative would be the cupellation of metal containing not only not the one-thousandth part, but as low a proportion as one-thirty-thousandth part of silver. By a method, however, discovered by H. L. PATTISON of Newcastle-on-Tyne, so small a quantity as one ounce of silver per ton of lead may be recovered with advantage. This beautiful process—like many others the result of an accident—was discovered in 1829. It is founded on the circumstance that an alloy of lead and silver, when cooled with occasional stirring, so as to be at or near the point of solidifying, crystallizes to some extent; and the part so crystallized is found upon examination to contain a very much smaller quantity of silver than the fluid matter which remains, or than the original alloy.

The application of this principle, which is known as *Pattison's process*, is extremely simple and manageable. Generally a series of eight or ten cast-iron pots, each capable of holding about five tons of molten lead, are arranged in a gallery of brickwork with a fire-place beneath each. The middle one of the range is charged with *original* lead, varying, as to the quantity of silver, from twenty or more ounces per ton to two. When the whole is melted the fire is withdrawn, the surface of the metal is carefully skimmed, and the fluid matter stirred by means of an iron spatula. After a brief interval, crystals begin to form and fall to the bottom of the pot, whence they are removed by another workman with a perforated ladle; all the fluid metal being separated by shaking the contents of the latter, which the workman effects by springing the handle on the edge of the pot. These crystals are deposited in the next pot, to the *right* of that in which the metal is first melted, in proportion as they are formed, till about the four-fifths of the weight taken has been transferred. The remaining one-fifth, which is now considerably more enriched with silver than at first, is ladled out into the first of the series towards the *left* hand. A new charge is again put into the middle pot, and transferred in the same way to the right, which may be designated No. 2. When enough of metal has been ladled into the latter to constitute a charge, it is in turn heated, and the crystallized lead melted, after which the process of separating the lead, after it has crystallized, is proceeded with as before, allowing about a fifth to remain, but which is transferred back to

No. 1. In this way the operations are conducted, till the whole of the pots come to be filled with metal holding more or less silver, according to their position in the series, at which time the work may be carried on with the whole, the poor metal passing always to the *right* from the extreme *left*, and that which is rich in silver traversing the pots in the opposite direction. Hence it follows that those to the right must contain metal which is being gradually deprived of silver, while that in the series to the left, must become richer in silver as they recede from the middle one.

During the working of the metal in the vessels, the ladles which are employed are apt to become chilled, as well during the draining of the crystals as when they are withdrawn from the fluid metal for any length; in either case the perforations being stopped by the fluid alloy solidifying in them, and to prevent or remedy this the temper pots are employed. These are about two feet in diameter, and filled with melted lead, the temperature of which is much more elevated than that in the working-pots, so that when the ladle is cold, or its grate obstructed by pellicles of the cooled metal, its immersion for some minutes in this pot will heat it to the proper degree, or free it from the obstructions referred to. Very little attention is necessary to comprehend how the purification from silver may thus be effected, and how the operation, with some slight attentions, cannot fail to be successful. The principal point to be attended to, apart from keeping the metal well stirred with the slice, and carefully removing the crystals, is the regulation of the heat, and which should merely border on the melting point of lead. When beyond this, very few crystals will form, and the process will be slow; practice, however, is the best guide in this particular. The following analyses of the assortments in this process may not be uninteresting:—

	Skimmings	Skimming reduced.	Market crystals.	Market lead.	Rich lead from crystallizing process.
Lead,	98.10	99.72	99.9	99.9	99.8
Antimony, ..	0.28	trace	trace	trace	trace
Copper,	trace	trace	trace	trace	trace

Lime,	0.22	—	—	—	—
	100.00	100.00	100.0	100.0	100.0

It is to be supposed, however, that a greater or less proportion of silver is contained in all the above, although it is not taken into account in the analyses. The concentration of the alloy is not carried on beyond three hundred ounces per ton at the works above-mentioned. When the silver has accumulated to this proportion, the rich lead is cast into bars about two inches square, and is known by the term *lead riches*.

PATTISON'S invention is now applied in almost all the lead works of the United Kingdom, and within the last ten years, it has been adopted in the principal lead foundries of France, Spain, and Prussia.

Cupellation of the lead riches.—This operation is performed in a furnace of the reverberatory class, having a contracted bed of a particular construction, and designated the *cupel*, or *test*. This apparatus, with the

whole process of cupellation, is fully described at page 284, under the article GOLD. At the smelting works of Messrs. WALKER, PARKER, and Company, where the *riches* holding about three hundred ounces of silver to the ton are cupelled, the process is continued in the same furnace till the last traces of the lead are removed, and the silver is left pure. In the eight refiners at this establishment, there are produced weekly from six to

eight bars of silver, each weighing a thousand ounces. The litharge which does not find its way into the market, is reduced in the reverberatory furnace, by mixing it with small coal or slack, and eliquating it on the bed, which is coated with slack to the depth of two or more inches. In the refining process, the products obtained besides the silver have the following composition at the different stages of the process :—

	Unfallen litharge, common.	Fallen litharge, common.	Fallen litharge, best.	Test bottoms.	Fumes from refining furnace.
Oxide of lead,	99·7	99·6	99·7	59·60	97·00 carbonate of

USES.—Such are the processes resorted to for the extraction of lead from its ores; but before it finds its way into the industrial arts, it is converted by mechanical contrivances into the necessary forms. These are, for the most part, sheets and tubes; the former being employed largely in architecture, for protecting the roofs, *et cetera*, of buildings, for the lining of tanks in which water is retained, for the construction of evaporating pans, sulphuric-acid chambers, and numerous other purposes. Pipes, on the other hand, find their application in conducting and distributing water, liquids, gases, *et cetera*. And, latterly, lead has been spun into wire, in which state it has been found useful for horticultural purposes, by the resistance which it offers to atmospheric influences. It also enters into various other compounds of a metallic nature, and by its peculiar properties, confers great advantages.

Lead is manufactured into sheets by means of rolling, combined with pressure. The melted lead is cast into a heavy plate six square feet, or more, and about six inches in thickness; and when sufficiently cold to admit of its being lifted by the crane, it is placed on the bench where the heavy iron rollers are situated, and passed under them repeatedly, backwards and forwards, till it is reduced to the desired thickness. By means of screws the rollers may be adjusted at any required distance from each other. At the rolling department of the Dee Bank Works the heavy cylinders are eight feet four by twenty-two inches diameter, and the lead is reduced sometimes to only the sixty-fourth part of an inch in thickness.

The works at Chinese Lead Valley—the pipe-founding department of the same firm—are on a similar scale of magnitude and elegance; and the old process of producing pipes by drawing and rolling is quite discarded. Hydraulic pumps and properly-arranged dies—of which there are a series, producing lead pipes from the smallest gas-pipe to conduits three and four inches internal diameter—may be seen at work, and capable of producing any desired length of piping, of the most regular and homogeneous thickness and quality throughout. Without going further into the details of these very beautiful mechanical contrivances, the subject may be here closed so far as the smelting, purification, and manufacture of lead is concerned.

ALLOYS.—Lead enters into the construction of several alloys, many of which have been already referred to—see ANTIMONY, BISMUTH, *et cetera*, *ante*;—and pewter, or solder, so largely employed by the plumber, is a combination of this metal and tin, in the proportion of two parts of lead to one of tin; sometimes, however, the proportion is varied, according to the requirements of the plumber.

Shot-metal.—Another alloy of lead is in very general use for lead-shot, and is a combination of this metal with arsenic. Shot-metal generally contains also portions of antimony and iron; since lead which is of inferior quality, owing to impregnations of the latter kind, is reserved especially for this manufacture. Arsenic, however, being the recognized alloying metal, the others are not noticed, although their presence affects the proportions in which the arsenic is to be added. Generally, the limits are from three to eight or ten parts in a thousand; the lesser quantity being employed as the lead is more ductile, and the larger when it is hard. The arsenic may be incorporated with the lead while in a state of fusion, either in the form of arsenious acid—*white arsenic*—or of orpiment—*sulphide*; and by the reaction which follows, the arsenic is reduced to the metallic state and combined with the lead; while a portion of the latter is thrown off as sulphide or oxide of lead, according to the nature of the arsenical body employed.

To prepare shot-metal, a quantity of lead, amounting to two or three tons, is melted in a pot; and when the heat has been pretty well raised, the surface of the metal near the rim of the pot is strewed with ashes or powdered charcoal, and the arsenic is introduced in the centre, and stirred with the metal briskly; the pot is then covered, and left so for some three hours. During this time reduction of the arsenical compound takes place, and an alloy of arsenic and lead is formed. With a good quality of lead, the proportion varies from twenty to twenty-eight pounds of arsenic to the ton of metal. This quantity, however, is not combined; for, on removing the cover from the pot, and stirring the whole with the slice or spatula, a large quantity of the arsenic is thrown off with the litharge which is produced. Sometimes orpiment is used, and in small but successive quantities, stirring after each addition. The alloy

is tried by letting a little of it fall through a perforated cullender into water; if the particles thus produced present a lenticular appearance, the proportion of arsenic is too small; but when they are flatter, or hollow in the middle, or elongated, it is an indication of there being a deficiency of arsenic—the proper degree of saturation is arrived at when the globules are round.

When, by this proof-test, it is judged that the alloy is properly saturated with arsenic, the whole is cast into bars, and raised by an endless chain to the top of a high tower, where it is melted in a small pot, and cast in perforated cards fitting into a frame in the centre of the tower. Some expertness is requisite on the part of the founder in maintaining the lead at the proper degree of heat, and also in allowing a film of oxide to form on the interior of the card, through which, in passing, the metal becomes disposed into grains as it parts from the card. Though the management of this part of the operation is deemed important, doubtless it serves only to cool the metal; for if it were to pass through in a too liquid state, it would assume an elongated form, and not globular. There are, of course, for the various kinds of shot, special cards, with perforations corresponding to the size; only that the aperture in the card is much smaller in diameter than the globule of metal which is formed by passing the metal through it. At the base of the tower is a circular basin, five or six feet deep, containing water, and into this the shot falls. When the smaller shot is being cast, the temperature of the metal is somewhat higher than for the larger kinds, such as those known by the letters A, A A, and A A A; B, B B, and B B B; with the latter the metal is said to have acquired the proper temperature when a straw plunged into it will not char, but acquires a perceptible brownish color. The cards used at the Chester Works are rectangular, and about twelve inches by eight; in other establishments hemispherical disks are used for casting the shot; but these are not so convenient as the flat-bottomed cards.

The next step in the process is the removal of the shot from the well, and drying it on a rectangular stove, the top of which is of cast-iron, heated by a fire; on this it is moved about till all traces of moisture have disappeared. It now presents a greyish-yellow aspect. To assort the grains according to the respective sizes, the dried article is put into a long perforated copper cylinder, the perforations corresponding at regular distances with the size of the shot; and beneath such divisions boxes, marked Nos. 13, 12, 11, 10, *et cetera*, for the reception of such as fall through, the smallest being first, and the larger approaching the further extremity, where the kind indicated by B B B are received. A revolving motion is given to this cylinder; and besides, at each revolution, a clapper is made to fall against it on the top surface, so as to knock out any grains which may remain in the perforations. During this process the appearance of the shot is slightly altered on account of the friction; but still it retains its dull, grey aspect. To give it the bloom, it is introduced into a cylinder by a door, together with a small quantity of blacklead plumbago, and the whole made to revolve for some time; and when taken out, it is

found to have assumed the well-known dark-grey lustre or polish peculiar to this article.

Before it is ready for use, however, it has to undergo another treatment, by which the defective grains are separated, and none but the truly circular find their way into the sportsman's belt. This is done by a very simple, but ingenious and effective contrivance. An inclined plane, slightly levelling to the sides, with a box or receptacle for the shot to be tested at its head, and the central portion of which is perfectly level, serves to make this assortment. A small aperture in the bottom of the box, and partly closed by a slide, allows the shot to roll out upon the middle of this table, after which it descends the incline. If the grains be perfect, they move on the middle space till they finally fall with a bound into the box placed in the front for their reception; but the least inequality causes them to deviate towards the sides, where they drop off into the receptacles ready for their reception, whence they are removed to be again melted and recast. The perfect shot is put up into twenty-eight pound bags or packages, ready for the market. In the establishment of WALKER, PARKER, and Company, about ten tons are manufactured weekly on an average; the shot-founding department is unique in the extreme.

Lead is capable of entering into combination with all the metalloids in one and multiple proportions, and of giving rise to bodies which are saline or salifiable, according as the radical combined is capable or not of generating salts. Thus, with chlorine, bromine, fluorine, and sulphur, salts are formed; whilst with oxygen, it constitutes several compounds, of which one is salifiable, others neutral, and finally, a third class, under peculiar agency, manifest acid properties.

OXIDE OF LEAD—Syn. Litharge—*Massicot*, *Litharge*, French; *Glüss*, *Bleioxyd*, German.—There are several compounds of lead and oxygen known to chemists, such as the *sub* and *protoxides*, the *sesqui* and *peroxides*; but all are not of equal interest to the manufacturer. Indeed, of these only the protoxide and the peroxide of lead have been recognized as articles of commercial industry, although, for the most part, more or less of the sesquioxide finds its way adventitiously into both articles.

The protoxide may be prepared in the pure state by heating carbonate or oxalate of lead at a dull red heat in a crucible, in which a current of air is made to circulate, or in an open dish. Here the salt radical is dispersed, and there remains a straw-yellow substance, which is pure oxide of lead, provided the salts submitted to the process contained no adulterants. When the temperature at which it is produced is elevated, it assumes a brownish-red color, which in part disappears as it cools. It is very heavy, and on being fused and allowed to cool, it forms itself into crystals, which, if the refrigeration be sudden, appear as scales; but if gradual, they assume the form of yellow, translucent, hexagonal tables. Oxide of lead is slightly soluble in water, producing solutions which have a feeble alkaline reaction. In potassa or soda liquor, the oxide is easily dissolved, and in this reaction doubtless assumes the nature of an acid, and produces a plumbate of the alkali. If, however, the solution

be allowed to remain for some time exposed to the air, the heavy oxide separates completely, and is ultimately found in dodecahedral crystals. It possesses very powerful basic properties, and is capable of producing neutral saline bodies with the weakest acids. It also combines with many of the acids, in proportions to constitute soluble subsalts, which manifest an alkaline reaction. In the heat it vitrifies boracic and silicic acids, whence its use in the manufacture of glass, pottery, *et cetera*; with oils, also, it seems to enter into peculiar combinations, which confer on them the property of drying rapidly on exposure to the air. Oxide of lead is readily decomposed when heated with carbonaceous or sulphurous matters, metallic lead being formed, and carbonic or sulphurous acid. When obtained by precipitation of the nitrate or acetate of lead, by means of an equivalent proportion of potassa or soda, it assimilates water, forming a hydrate, which rapidly absorbs carbonic acid from the air. Oxide of lead is highly useful to the chemist, as it constitutes definite salts with most organic acids, and thus enables him to isolate the latter in his researches, or bring them into a convenient form, for the determination of their equivalents and constituents. Being so generally employed, it is evident that the greatest attention should be given to the determination of its equivalent. Such has been the case, and repeated estimations of its constituents and combining weight have led chemists to fix the latter at 112, its composition being as follows:—

	Centesimally.
1 Eq. of metallic lead,	104
1 Eq. of oxygen,	8
1 Eq. of oxide of lead,	112

The anhydrous oxide is represented, therefore, by Pb O, and the hydrate by Pb O, HO.

The preparation of oxide of lead, on the large scale, is effected by heating metallic lead in the air, and removing the film of oxide which forms upon it. The first stage in the manufacture of minium is the preparation of this oxide; for, as stated, the metal is oxidised, at a low temperature, with a current of air passing over it. This is the *massicot*, but it does not find its place in the market, although it is more adapted for many applications than the other form of the same body known as litharge. This may arise from the circumstance that, for the production of the massicot, an especial oxidation of the lead should take place, and at some expense; and besides, being finely divided and friable, it rapidly attracts carbonic acid from the air, and passes into the state of carbonate. On the other hand, the litharge is obtained as a secondary product, the production of which involves the manufacturer in no extra costs, and it resists air and moisture much better than the massicot.

Litharge is obtained by the oxidation of lead, raised to a high degree of heat by a blast of air, the temperature being so elevated as to fuse it. When the metal is pure, the litharge which it yields, with the exception of the first skimmings that constitute the abstrichs, is of good quality. Obtained according to this treatment, litharge is a yellowish, or yellowish-red, compact substance, crystallized in six-sided plates, and semi-

transparent. It was customary to designate the yellow and reddish compounds by the terms *silver* and *golden* litharge, from the supposition that the latter contained some precious substance, to which the difference of color was owing. It is well known, however, that a slight superoxidation of the lead, which takes place at a lower heat or during the cooling, when much exposed, is the only difference. Litharge is used in painting as a pigment, for the production of acetate of lead, and sometimes in glass and pottery establishments.

Minium, or *red lead*, is another oxide which forms a special branch of manufacture, and one which, to produce a superior article, requires much care in the operations, and also in the selection of the materials. The purest lead is required for this manufacture. If it contains antimony, iron, silver, or such substances as are met with in inferior qualities of metal, the minium which it affords is never of a good color; besides, it is rejected by the manufacturers of flint-glass, owing to its giving the metal a peculiar dulness, which they endeavor to avoid. The metal selected from the products of the purest ores is melted in a reverberatory furnace, with a spacious hearth or bed, ten feet by seven, and having a high bridge and arch, so that the flame and gases revolve from the latter to the metal over the entire space. The fire is never urged to render the interior hotter than a very dull redness. In consequence of the air passing into the furnace through the fire, and by the other apertures, a covering of oxide forms on the surface of the bath; this is raked aside by the workman, and a fresh surface exposed, which in a short time becomes coated as before, and cleared in the same way. This operation, which is called the *drossing*, is continued till the whole of the lead is oxidised, and a yellowish powder of oxide results. The process occupies about twenty-two hours. As the massicot, or litharge, is increased in quantity, it is carefully disposed into channels for the purpose of allowing contact of the metallic portion with the air, to favor its oxidation. After the metallic character of the lead introduced has disappeared, the oxide, or dross, is spread out on the sole, and turned occasionally, in order that any particles removed during the drossing in the semi-metallic state, or in that of suboxide, may be wholly converted into litharge. When completely oxidised, it forms a layer of two and a half to three inches thick on the bed of the furnace. At this period the powder is raked out into iron waggons at the working door, and conveyed to the coloring furnace, which is in every respect similar to the last, only that its temperature is somewhat lower. Here it is spread on the sole in a layer, and left exposed to the oxidising effects of the air passing through the fire in a partly undecomposed state, and also to that which enters at the doors, which, unless the temperature be too low, are left half or quarter part opened. To expedite the oxidation—to which the tint is to be attributed—the surface is renewed frequently, and sometimes enlarged by artificial channels, made in it with a pronged rake. Great attention is necessary to maintain the heat of the furnace at its due degree—that is, somewhat below dull redness, or between 550° and 600°—also, in exposing a fresh surface till the proper shade of color is attained.

Forty-eight hours are occupied at the Dee Bank Works, where a remarkably fine article is produced. The *red lead*, which now presents a beautiful bright-red hue, is removed, ground under iron disks, circulating in a revolving flat iron tray, and packed in casks for the market.

Minium has a very doubtful composition, and is regarded by many chemists as a mixture of protoxide and of sesquioxide of lead PbO , Pb_2O_3 , whilst others maintain that it is a mixture of oxide and peroxide, the latter acting as the negative radical of a salt $2PbO$, PbO_2 ; and some hold that it is neither one nor the other, but a compound containing four equivalents of metallic lead, and five of oxygen, and which may be represented by the formula Pb_4O_5 or $3PbO$, PbO_2 .

Minium is employed largely as a pigment in the paper-hanging manufacture, to communicate a rose, orange, and aurora tinge; for painting also it is in general use, and in the manufacture of glass and many kinds of pottery-ware, it is an indispensable ingredient, from the property it possesses of forming vitrifiable compounds with silica and alumina, which unite with the other silicates of the glass and ware, and thus render the body perfectly homogeneous.

There is another oxide of lead, known as the puce-colored oxide, which has not a general application, but is useful sometimes in analytical chemistry. Its gravity is 8.902 at 98°, and its composition

		Centesimally.

Symbol PbO_2 . This body does not combine with acids; it is readily decomposed in the heat into oxygen gas, and protoxide of lead.

The salts of lead, important in a manufacturing sense, are the carbonate, the acetate, and chromate; the sulphate is sometimes prepared. Of these the acetate has been already described—See page 43, Vol. I.—so that only the others require to be noticed.

CARBONATE OF LEAD.—Syn. *White lead*—*Ceruse*, —*Blanc de plomb*, *Blanc de ceruse*, *de clichy*, French; *Bleiweiss*, *Kohlensaures Bleioxyd*, German. This substance is found in nature in small quantities, mixed with other compounds of the metal, in lodes of lead minerals—for instance, in Cumberland, in Scotland, in the Hartz, and in Bohemia; it is also found in many departments of France, such as at Saint Maria-aux-Mines in the Vosges; at Saint Saurier in Languedoc; at Poullaquen in Brittany, *et cetera*. Large deposits of it have been discovered in America, as at Mine à la Motte, and other districts.

In all these localities it generally happens that the carbonate is found associated with other minerals which constitute the bulk of the lode. In these cases it is almost always in the crystalline state, the figure being derived from the rhomboidal prism in some varieties, while other kinds appear as an agglomeration of very minute particles; and it is occasionally found in compact masses. Almost every variety is white or brownish-yellow, transparent, and very refractive, having a specific gravity varying from 6.070 to 6.558. The

natural product is never employed for any of the purposes to which white lead is devoted in the arts, and hence all that is consumed in this way is of artificial production.

Preparation.—Pure carbonate of lead may be prepared by precipitating a solution of pure acetate, or of nitrate of lead, with another of a carbonate of an alkali, filtering off the solution, washing the residue thoroughly, and subsequently drying the mass. So obtained, it is a white powder almost insoluble in water, but dissolved with evolution of carbonic acid in nitric, hydrochloric, acetic and other acids, which yield with this base soluble salts; those salt radicals, which constitute with the metal or its oxide insoluble salts, decompose the carbonate, set free the carbonic acid, and form an insoluble compound. Such are oxalic, sulphuric, and hydrosulphuric—sulphide of hydrogen—acids, *et cetera*. Even water impregnated with carbonic acid readily causes the carbonate of lead to dissolve; but, in this instance, there is no escape of carbonic acid, but an assimilation of that contained in the water. By the action of heat, as already signified, it is convertible into litharge or minium according to the intensity of the caloric and the duration of its application. Produced according to the above method, it is a compound of one equivalent of oxide of lead and one of carbonic acid; sometimes, however, it is met with as a basic carbonate—that is, a carbonate wherein is contained a proportionate quantity of base without being assimilated with its equivalent amount of carbonic acid. Sometimes when prepared on the large scale by certain processes, more or less acetate or sulphate and oxide of lead are found in it; but their quantity will be proportionate to the purity of the compounds taken, and the care bestowed in the manufacture. It consists of—

and its chemical symbol is PbO , CO_2 .

The manufacture of white lead, though of long standing, and comparatively very extensive, has been, till within a few years, very fatal to those engaged in the operations. M. DE RONLZ states that during the eight years ending in 1844, the number of patients admitted to one hospital—the *Hôpital de la Charité*—attacked with *lead colic*, amounted to one thousand one hundred and sixty-three, of which number four hundred and six were persons employed in the manufacture of white lead, and three hundred and eighty-five were painters. It is pleasing to state, however, that endeavors are now generally made by proprietors of white lead factories to remove the causes of the frightful mortality so long produced, by adopting proper machinery for the execution of such parts of the business as prove most dangerous to the health of the workmen, and by enacting rules which enforce the observance of every precaution on the part of the employed.

Carbonate of lead can be prepared in several ways, and of late years various methods have been introduced for its production, all of which may be said to be

modifications of two standard processes—namely, the Dutch method, in which the reactions are effected by operating on metallic lead with acetic acid, and decomposing carbonaceous matters at a comparatively elevated temperature, and without any other moisture than steam; and the other, wherein the carbonate is thrown down from a solution of basic acetate of lead by transmitting carbonic acid through it. These modes offer an unequal degree of advantage to the manufacturer; for although the second is the more rational, as will be seen afterwards, yet the salt produced is different in its molecular construction from that obtained by the first method, and on this account does not suit the wants of the painter or color-maker so well. The particles of the precipitated compound are comparatively large, and appear of a semi-transparent crystalline form; whilst the other is amorphous, its formation being effected by the successive decomposition of the smallest possible quantities of the basic acetate. Hence it is more finely divided, and presents a larger number of particles in a given bulk than the white prepared by precipitation. In principle, however, the two methods are the same, since the carbonate is produced in both by the decomposition of a basic acetate of the metal, the excess of the base being removed by the carbonic acid, and leaving a neutral acetate to react further on the metallic plates in one case, and on litharge in the other, so as to reconstitute a basic salt, which, as soon as it is produced, is acted upon as before. In this way the work proceeds; first, a basic salt is formed, and is decomposed, but yields by that reaction a body capable of producing the first substance an indefinite number of times. The nature of these changes will be more easily comprehended from the following equation, which explains them with special reference to the Dutch method:—

That is, with one equivalent, or sixty parts by weight of pure acetic acid, three equivalents, or three hundred and twelve parts of lead, and three equivalents, or twenty-four parts of oxygen,—one equivalent of the tribasic acetate is obtained. The second part of the process, so far as its chemical bearing is concerned, may be briefly explained thus:—

In this decomposition, three hundred and ninety-six parts, or one equivalent, of the basic acetate, is represented to yield two equivalents of its base to the carbonic acid present, thus producing two hundred and sixty-eight parts or two equivalents of carbonate of lead, and leaving the third equivalent of oxide combined with the whole of the acetic acid. The neutral acetate thus produced takes up two equivalents more from the metal unacted upon, and produces another

proportionate quantity of basic salt, which undergoes the metamorphoses above represented.

To bring about in the readiest and most inexpensive manner the modifications above shown, is the object to be aimed at in the manufacture, provided the product has that degree of divisibility and opacity which is possessed by that recognized as first quality in color and body.

Dutch Method.—The first step in the old Dutch process, consisted in casting the lead into sheets in the following manner: the metal being melted was poured out upon iron plates, and as soon as the surface began to exhibit signs of consolidating, the iron plate was inclined, and the fluid lead allowed to flow back into the pot. The sheet of lead which was thus left was removed, the iron plate cooled in water, and another sheet cast in the same way. In this manner several hundredweights of lead were converted into thin sheets, in twenty-four hours, varying in thickness from one twenty-fourth to one forty-eighth of an inch. The plates so formed were bent in the middle, the bend being occupied by a slip of wood. A number of these was arranged in a wooden box, four and a half to five feet long, twelve to fourteen inches broad, and nine to eleven inches deep; the sheets being so disposed as not to touch one another, nor the sides or bottom of the box. An acid liquor, consisting of four quarts of acetic acid, and four of wine lies, was also put into the same receptacle, and the cover placed securely on. Sometimes the acid mixture was varied according to the ideas of the manufacturer. When a number of these was so prepared, they were introduced into a stove-room, where the heat was sufficiently elevated to cause the evaporation of the acid, so as to bring it into contact with the sheets of lead. The stove-room was of such a capacity as to receive about ninety boxes, and had only one door. A temperature, averaging 86°, was maintained during fifteen days, in which time the plates were acted upon by the acetic acid, and the carbonic acid from the fermentation of the wine lies, assisted by the air and moisture, so that they presented a thickness of a quarter of an inch, whereas, before the operation, they did not possess a twentieth. After this the plates were shaken, in order to detach the crust of white lead, which was subsequently ground and washed. Horse-dung was sometimes employed in this operation, to raise and maintain the temperature by its fermentation, in which case the covers of the boxes were secured by pasting paper round their edges, in order to guard against the discoloration of the white carbonate by the sulphide of hydrogen given off during the decomposition of the dung.

Such is an outline of the old process pursued in this manufacture; but for many years it has been conducted on a more extensive and simpler plan, which was first adopted by the Dutch themselves, and from them has been borrowed by the French and English. On this improved system, the work, instead of being performed in boxes, is executed in large rectangular spaces, inclosed by stout walls constructed of bricks or masonry, within which pots of acid, containing coils of sheet lead, are piled in *stacks*.

The several stages in the manufacture of white lead, by the new Dutch process, may be divided into the casting of the metal, the erection of the beds, or *heights*, in the *stack*, the taking down of the same, the screening or unscaling of the crusted lead, the grinding of the scales, the grinding of the white lead in water, the exsiccation, the grinding of the white dried loaves, alone or with oil, and the packing.

Casting the Metal.—A quantity of metal, of that quality which is deemed the best for the production of white lead, is put into a cast-iron boiler or pot, and melted; this boiler is very often exposed in the foundry, yet the method of inclosing it in a hood is to be preferred; for then, not only are the workmen protected from any fumes which may arise from the melted bath, but from spiritings which follow the accidental introduction of moist lead from the screening or unscaling apparatus. Fig. 335 is a vertical sectional view of this pot, showing the position of the hood used as a protection to it. In this figure, A is the pot wherein the lead is melted, and which is surmounted by the hood, B, in connection with the chimney by the tube, c. D represents the fire, E the fire-door, and F an aperture in the hood, which can be closed at pleasure, by a

Fig. 335.

double sheet moving in grooves at either side. These plates are slid backwards, when the metal, which should be only a few degrees above the melting point, is to be drawn out in ladles to be cast in the ingot plate moulds. Thin plates, from sixteen to twenty-four inches long, four wide, and from two-fifths to one inch in thickness, are thus formed, which are afterwards rolled into a coil, to be introduced into the pots, where they are exposed to the chemical

effects of the acids and air in the subsequent part of the business. These pots have in the interior a ledge, *a*, whereon the coiled plate is supported, when they are charged in the stack. Latterly many manufacturers, and especially the English, employ the lead in the form of *grates* or *crates*, as it presents a greater surface, and permits a freer circulation than the former. They are formed by casting the lead on an iron slab, grooved by parallel, longitudinal, and transverse gutters, an inch apart, into which the fluid metal runs.

Construction of the Stacks.—The arrangement of the *stacks*, or *dung-pits*, is represented in Fig. 336, which

Fig. 336.

is a vertical section, filled with the several layers of dung, acid pots, lead plates, and boards successively. A represents the wall, and B the roofing which inclose these spaces. A corridor runs along the sides, in which is a railway, D, for transporting the waggons of dung, boards, *et cetera*, to the space where required. In the front of each of these a door, E, rises the whole height of the stack, to facilitate the introduction of the materials, but which is closed by boards placed cross-wise as the several beds are erected. The dimensions of these stacking-spaces vary in different factories, it being supposed by some parties, that the conversion succeeds best in large stacks, whilst others maintain that stacks of lesser dimensions afford better results; and, for reasons which will be presently adduced, doubtless stacks of a medium size operate best. The dimensions usually given average from thirteen to sixteen and a half feet in length, thirteen to fifteen wide, and about twenty high; and in extensive factories such a number are constructed as will permit the gang of workmen to erect and dismantle one daily, the others being in a proportionate stage of advancement as they are being approached. In this particular part of the manufacture very little improvement has been effected on the method adopted years ago.

These spaces are filled up with material, by a gang of workmen, who are generally paid a definite sum for the erection of the stack. A bank of dung which has been used previously, is raised round the walls of the pit, a foot in breadth, and of the height of sixteen to eighteen inches; in the space thus inclosed, fresh horse-dung to the depth of sixteen inches is spread. A layer of pots, eight inches high, and nine and a half diameter at the top, are placed side by side, till the whole space with the exception of the dimensions of the first embankment, *a*, is covered. Each of these pots, which are glazed in the interior, is charged with a gill and a half, or from that to two gills of common acetic acid, and a roll of sheet-lead; excepting a few which are placed towards the middle and at the corners, that are three quarters filled with vinegar. Ten to twelve hundred of these pots are placed in one floor, or *height*. After arranging the pots and supplying them with the necessary quantity of acid, and resting a spiral of lead on the interior ledge of each pot, another bed is formed, composed of triple or quadruple sheets of lead, laid horizontally upon the first, till the whole surface is covered. Planks, or stout boards, are now laid on the latter, and upon these another layer of lighter boards is placed, as seen at *bb* in the foregoing figures. A second bank of old dung is then formed round by the walls, and a new bed of dung spread as described, upon which a second layer of pots is deposited, and charged with acid and lead, in the same way as the last. This process is repeated, alternating the dung, the pots, lead sheets, and boards, till the pit is filled; only that the layers of dung are only twelve inches thick, from the first till the top covering, which is made with old dung, and of a thickness of twenty to twenty-four inches. Eight heights or layers of pots usually constitute the stack, but sometimes ten are introduced. At either end of the several beds, alternately, a space is left vacant, for instituting a draught from one bed to another, and increasing, at the same time that it equalizes, the effect. Every stack when completed contains for each bed or height, together with the boards, dung, and pots, about seven gallons of vinegar, or fifty-three in the entire stock of eight beds, and from one ton four hundreds to a ton and a half of lead, making from nine and a half to twelve tons of metal in the whole. Four men can lay two heights in a day, so that in four days they can complete a stack. In many establishments, gas is especially manufactured for lighting the premises, so that in winter the operations can be carried on with artificial light.

A period, varying from five to six weeks, is allowed for the conversion of the lead into carbonate to the fullest extent.

Although in those establishments where horse-dung is employed, it is reported that the health of the workmen does not suffer in consequence of the offensive smell which is evolved from these masses of decomposing matters, still the method adopted in England of using spent tanners' bark instead, is much more agreeable; and although in its operations it is slower than the former, the product is not liable to be darkened by sulphide of hydrogen, which the dung evolves during

the decomposition of its sulphur compounds. When tan waste is used, nine or ten weeks are required to carbonate the metal. Whilst the materials remain, the several layers of dung or tan enter into a fermentation, which determines a rise of temperature sufficient to determine the evaporation of the acetic acid and water from the pots; and these vapors, coming in contact with the metal in the presence of the oxygen of the atmosphere, effect its oxidation, and the formation of an acetate of lead, in which there is an excess of base. Carbonic acid is likewise evolved from the eremacausis of the organic substance, which decomposes the film of basic acetate, setting free a neutral salt to take up fresh quantities of the oxide of the metal, which is likewise broken up as before. In this way, the production of carbonate of lead proceeds in exceeding small portions; but the operation being continued for a length of time uninterruptedly, and a vast area of lead being operated upon, a considerable quantity is produced.

It is the minute state of division of the carbonate, arising from its slow and gradual production in small portions, which distinguishes the white lead produced in this way from the same compound when it is obtained by precipitation from the solution of the basic acetate; for in the latter case the particles are larger and semi-crystalline, and, when used with the brush, the white lead fails to cover the same space with a coat of opaque paint, as will an equal weight of the carbonate obtained by the Dutch method. This opacity and extreme division constitute what in the language of the trade is termed *body*; and notwithstanding that other modes of preparation, more desirable in a sanitary point of view than the one under consideration, have been suggested, yet the want of this body in the manufactured article condemns it in the painter's estimation.

A great drawback upon the Dutch method of operation is the irregular manner in which it proceeds; for sometimes the temperature in the centre of the stack is as high as 194° and even 212° , which causes the rapid evaporation of the acetic acid, and, the circulation of air being imperfect, a corresponding corrosion is not produced; on the other hand, the portion towards the walls often does not acquire sufficient heat to evaporate the acid, and, therefore, the production of carbonate is not as great here as might be expected. The best results are obtained when there is a due degree of circulation of air, and a temperature of from 100° to 120° is sustained.

Unscaling.—When the time necessary for conversion of the lead into carbonate has elapsed, the dismantling of the stack is begun. The superior layer of material is thoroughly removed, and afterwards the plates of carbonate of lead are exposed by taking off the boards and planks which had protected them. This being done, the carbonated plates and spirals in the pots are taken and deposited in small wooden boxes, in which they are carried to the part of the factory where the unscaling or screening is proceeded with. In the old system this part of the work proved eminently unhealthy; for the method pursued was calculated to load the atmosphere with a great deal of impalpable powder, which, being inhaled, poisoned the

operatives. The plates were taken up with the naked hands, and the crust of carbonate detached by striking them against one another; the larger part was thus removed, but a considerable quantity still adhered, and to detach it a number of the plates was laid over one another on a thick flag-stone and struck with a heavy mallet. Here the greatest danger was risked; for by the hammering of the plates, the surrounding air was loaded with the dust, which was productive of a double injury—that of a loss in the product, and of danger to the health of the workmen. Fortunately for the sake of humanity, science has come to its aid; and now, excepting in some isolated cases, the stripping of the plates is performed by machinery, which is so inclosed that no appreciable escape of the white lead takes place, and the air in the room remains pure and wholesome. At the establishment of M. LEFEVRE of Lille, in France, the following is the method adopted:—The men who take the sheets from the pots are protected by large lamb-skin gloves, in order that none of the lead may come into contact with the skin, and consequently they are not endangered, as no absorption can take place. The plates are brought in a small truck to the base of the machine, and lifted by means of an endless rope to which a bucket is attached, to a table, where the unrolled sheets which were in the pots, as also those resting upon them, are laid on an endless piece of leather, which carries them forward to a series of grooved rollers, between which they pass. The rollers reduce the matter to such a degree of division as to prepare it for the grinding-mills to which it is afterwards subjected. For this purpose it is first moistened, and then carried to the grinding-room, where it is passed under a number of horizontal millstones. Here it is ground and forced out into baskets by the centrifugal motion of the stones, through a sluice at opposite sides of the mill. From the baskets the fine paste is put into pots, and placed in the drying-house, where it remains for ten or twelve days.

The drying-house is a square apartment with solidly built walls, and furnished with shelves at particular distances; these are constructed of stout iron bars stretched longitudinally by the walls, and strengthened by uprights of the same metal. In winter, the apartment is heated by a fire of pit coal, surmounted by a huge canopy of cast-iron from which the calorific radiates to all parts of the room, thus raising the temperature of the air, and causing the expulsion of the water from the salt. In summer, the circulation of a current of air is sufficient to effect the desiccation, so that the mass of white lead contracts considerably, and also acquires such hardness as will resist handling. The loaves thus assume the form of the moulds, and as many of them as remain whole are taken out of these vessels, by inverting them on trays, which are afterwards deposited on shelves in another apartment, into which heated air is forced. Here a further quantity of moisture is expelled. Finally, the loaves are wrapped in blue paper, and put up in barrels for the market. The broken loaves are carried to a mill, where they are ground to powder, and packed in barrels, or made into paint by mixing with the ground white lead from eight to ten per cent. of oil.

Until these improved methods were introduced, the reduction of the white-lead to an impalpable powder presented the gravest disadvantages, besides being positively destructive to the health of the workmen. The grinding was generally effected under revolving head-stones, upon a cast-iron basin of the ordinary shape, the coarse material being introduced and withdrawn with the spade; and during this necessarily slow procedure, the dust arising from the agitation of the substance and its removal from one place to another, in the exposed manner in which it was done, had a rapid and injurious effect. It is the Editor's belief, that in most establishments of any repute, all these operations are now performed by machinery, and that to arrest any dust, water is employed where the various departments are not isolated from the remaining space.

The pulverization of the imperfect moulds is effected, in the factory already alluded to, by means of horizontal marble mills, enclosed by a metallic covering which is securely fixed in its place, so that any of the carbonate which might otherwise pass into the surrounding air is completely arrested.

Latterly, the French and Dutch manufacturers are adopting the English custom of compounding the white-lead with oil at once, and thereby preventing two grave inconveniences; for not only does the preparing of it in loaves and powder offer greater trouble to the manufacturer, but it is fraught with danger to the color-maker and painter, because rarely have the latter such arrangements as to effect the mixing without exposing the operator to the danger of inhaling the poison, and thus laying the foundation for lead or *painters' colic*. Till within the last few years they were generally compelled to perform this operation, and the frequent cases of lead poisoning gave rise to the popular term, by which the disease was recognized among this class of men. This danger is obviated now-a-days by converting the white lead into paint in the manufactories; it is done expeditiously and without risk in an apparatus entitled a *kneader*, somewhat like that used in large baking establishments. This is a cylinder, in which a square iron bar, furnished with arms, is fixed longitudinally. The latter is turned by means of a strap passing over a drum, and another in connection with the engine shaft. All the materials—white lead, and oil to the extent of eight per cent. of the lead compound—are introduced by the doors, which are firmly closed, when the machine is at work, by a lever, secured by a bolt. When the two are mixed the paste is drawn out, and if necessary passed through a grinding mill to render it more homogeneous.

Such is the general character of the arrangements in the well regulated factory of M. LEFEVRE of Lille. Here there is a large saloon at the disposal of the men, where they put on and divest themselves of their factory dresses, and perform their ablutions; and another which is used as a refectory, into which they are forbidden to enter in their ordinary working coverings. Gloves made of lambskin are supplied by the proprietor, and worn by all those who are exposed to handle or touch the white lead, so that the danger of absorbing any portion of the poison through the pores of the skin is avoided. All these precautions are not without their merited

return, since it is a rare thing, even in the course of several years, to hear of any ailment among the operatives brought about by the nature of their work.

On a par with the foregoing for the general arrangement, and the healthy atmosphere pervading it, is the factory of Messrs. WALKER, PARKER, and Company, previously mentioned. Here the arrangements for melting and casting the lead in crates are similar to those already described. The acetic acid is prepared on the premises. The stacks, also, of which there are thirty-four, are similarly constructed, only that the source of the carbonic acid and heat is tan, instead of the dung used by the Dutch and French manufacturers. It is usual to construct the beds of the several materials in the ordinary way, only that the layer of tan is somewhat thicker than if it were horse-dung. Another difference in laying down the bed of pots, with the exception of about two hundred to two hundred and fifty, is, that the lead is laid flat upon their mouths, in a layer of four, five, or six crates, each weighing about three pounds a voidupois. The pots, therefore, are simple internally-glazed vases, capable of holding a quart or thereabout, with the exception of the two hundred and fifty above alluded to; these have a ledge in their middle, upon which a coil of the crate lead rests, and are arranged round the circumference of the floor, and at intervals in the middle, for the purpose of supporting the planks, boards, and other overlaying materials. Acetic acid prepared from wood, and diluted so as to mark 1° on the acetometer, is poured into the pots, to the extent of about half a pint, excepting the larger pots which receive double the quantity. Proceeding thus with each layer, the stack is completed, and is left so for a period of eight or ten weeks. And here, it may be remarked, that the experience of the proprietors of the above works has proved to them, that with an acid marking 1·5°, or over, on the acetometer, the conversion of the lead into carbonate never proceeds satisfactorily, nor is the quantity nearly so large as when a weaker acid is employed; for in the former case too much neutral acetate of lead is formed, probably owing to the generation of carbonic acid and the circulation of air being imperfect, and partly passes off in the waters used in the preparation of the white lead afterwards.

In this mode of manufacture, no danger exists of the white lead being blackened with sulphide of hydrogen, but the greatest care must be taken to have the covering of each layer of pots perfect, lest some of the tan might fall through, in which case it cannot fail to produce a stain. Again, when the carbonisation is imperfect, the carbonate which is produced is of inferior quality, since it is largely mixed with a suboxide of lead, forming a bluish-grey coating on the unattacked metal. The only security against imperfect working in the stacks, is to employ a properly-diluted acid, to select a good quality of tan, and to effect a proper circulation of the air, since with bad tan, there is not sufficient fermentation to generate either carbonic acid, or heat to evaporate the acetic acid; and without the air to oxidise the metal, the repeated action of a small quantity of acetic acid, in producing a large amount of oxide of lead, is impeded. After the carbonisation of the lead,

the several layers of tan, wood, *et cetera*, are removed, when the pots will be found emptied of their contents, and the layers of crate lead swelled to double or treble their original thickness, owing to the formation of the carbonate of lead upon them.

The sheets are taken off, put into a small carriage, and conveyed on a tramway to the departments of the work where the parting of the salt of lead from the unoxidised portions of the metal takes place. Since the latter is the highest part of the machinery in the area where the cleansing, grinding, and other operations are effected, the railway mentioned is on the second story of the establishment.

Although in the works of Messrs. WALKER and PARKER, the hermetical sealing up of machinery is entirely dispensed with except in one particular, still, rarely is there seen an operation, which in itself is very dangerous, rendered so innocuous with such simple contrivances, as that of the preparation of white lead at the manufacture referred to. Here water is to be found almost in all parts of the factory where the parting and grinding is proceeding, and it serves most effectually to suppress the evolution of the minutest trace of white lead into the atmosphere.

The carriage loaded with the carbonated crates, is, when it reaches the working gallery, emptied into a hopper capable of being covered. This is surmounted by a water-pipe, terminating in a rose, which showers this liquid upon the lead. By the aid of fluted rollers, the crust of white lead is in a great measure detached from the metal, and both are delivered on the end of a rectangular ledge or trough, having a perforated zinc covering above its real bottom. On this there is always retained a quantity of water, and as the material is delivered from the rollers in the drum adjoining the hopper, a man with a small rake moves it back and forth on this with a view of detaching the crust, that was loosened and partly separated in passing between the rollers; the residuary lead still retaining some portions of white lead, is passed between another pair of channeled rollers, and falls upon another table like the preceding, where, by agitating with rakes on the perforated bottom of the trough, and the use of the water, the particles of lead remaining are thoroughly cleaned and removed to a receptacle, whence they are conveyed to the melting house and there recast into crates or pigs of *blue lead*. Whilst on the perforated troughs, the particles of white lead are assorted, and any metal as well as colored parts removed from that which is purely white. For this purpose considerable agitation and working with the rakes is necessary, but still as there is a sufficiency of water, there is not the least escape of carbonate of lead.

From these troughs the partly-drained salt is conveyed to the hoppers of a number of adjacent millstones, where it is abraded and given out from the sluice in a pasty state; these sluices deliver it into the boxes of other heavier mills placed below the former in a second tier. Finally, the white lead, thus reduced, passes through a third mill, and thence into a deep tub or vat, which also receives a stream of water from the pump; and by means of a rotating agitator the lead is so mixed with the water, that it is carried off in the sluice which

forms the outlet to the last vessel, to a series of large tanks or settlers, where the lead after a while precipitates to the bottom and leaves the supernatant water clear. After settling, the bright liquor is siphoned off into a sluice, which conducts it to a well, whence it is pumped up into the higher benches by a forced pump. In this way, the same water is available for a number of times, and each time it becomes purer and less liable to deteriorate the carbonate. The deposited white lead is then taken out with a ladle and put into flat-bottomed dishes, which are conveyed to the drying-house by the younger hands in the establishment. This is a room furnished with shelves of strong iron bars, well-supported all along the four walls; having a large iron casting in the centre, and which is heated by a fire placed outside the building. By the heat radiated from this casting, the temperature of the apartment is considerably elevated, and the moist white lead is dried in the course of a few days. It then appears as a pure white amorphous cake. To convert these into paint they are conveyed to a mill, and the powder passed through a bolter of the usual formation. Oil is next mixed with the ground white lead in a mechanical kneading-trough, and the paste ultimately passed through a mill, and the product packed into barrels for the painter. The mills for grinding the dried product, as well as the sifter, are secured by an envelope which permits no escape of dust; the kneader likewise is

securely closed, and the paint-mill like all the others, is almost enveloped in a box, which does not allow any of the matter to escape.

CLICHY WHITE.—Several years ago, THENARD established the principle, that when a neutral solution of a soluble salt of lead is put in contact with an excess of litharge, or oxide of lead, a basic salt is formed, which yields a part of its oxide to carbonic acid, the remaining portion forming a neutral salt with the acid. M. ROARD established a manufactory of white lead in which this principle was carried out by dissolving the litharge in acetic acid, obtained by the distillation of wood or vinegar, in order to produce the basic acetate 3 Pb O —a solution of 29° Twaddell, specific gravity 1.145—through which carbonic acid, obtained from the combustion of charcoal, coke, or limestone, was passed, with the view of throwing down two equivalents of the metallic oxide in the state of carbonate, and of leaving a neutral acetate of lead in the solution, ready to operate upon a fresh quantity of the litharge, and convert it into the basic salt mentioned.

The arrangements by which this process is carried on are seen in Fig. 337. A indicates a large tub, capable of holding four thousand four hundred gallons of liquid, in which the acetic acid is made to combine with the litharge, having an agitator, C B. When the solution attains a gravity of 29° Twaddell, it is drawn into the settling vessel, E, by the stopcock, d. The vessel, E,

Fig. 337.

which is constructed of copper plates riveted together, and has a capacity of four thousand two hundred gallons, is intended to intercept any particles of lead, iron, or chloride of silver, which might exist in the menstruum, and be carried over in suspension from A. From E the clear liquor is drawn into the decomposing vessel, ff, which is about twenty feet long, half this in breadth, and two feet in depth; it is replenished to the height of twenty inches, and holds about two thousand gallons. It is secured with a cover by clasps to the flanges of the side plates, as shown in the drawing. This cover is traversed by eight hundred pipes, which plunge to the depth of thirteen inches into the solution, the other ends being soldered to twenty branching pipes, which extend at right angles from a main, gg, at each side;

the latter is connected with the blowing apparatus, kk, which is supplied with carbonic acid by the furnace, charged either with coke or some other matter for generating the gas. The carbonic acid was at first obtained from

the combustion of charcoal; but at the suggestion of DUMAS, chalk and coke in the ratio of two and a half of the former, to one of the latter, was adopted with advantage. A small lime-kiln, DD, is used to burn this mixture, and the carbonic acid is drawn over through the pipe, a.

After the precipitation of the carbonate of lead, which generally requires twelve or fourteen hours, the contents of the tank are allowed to settle, and after this the solution of neutral acetate is drawn off into the

tank, *m*, and is hence transported by a force-pump, *p*, and a pipe, *n n*, to the tub, *A*, where it recombines with as much oxide of lead as it lost during the precipitation. In this way the neutral solution drawn off from *ff*, and which is found reduced from 29° to 7° Twaddell, can be made to circulate for an indefinite number of times, and be made the agent for the solution of the litharge, so as to bring it into a fit state for its conversion into carbonate by the carbonic acid. There is, however, a slight loss of neutral acetate each time owing to its being partly retained by the carbonate, and partly passing off in the washings, so that it is necessary in practice to renew the strengths of the solutions by the addition of a little acetic acid in the tun, *A*.

The deposited carbonate is removed after raising the cover by means of cords attached to the main pipe, *g g*, and pullies on the beam, *s s*, the clasps which secured it being unfastened; the white lead is brushed out through an opening, which is stopped at all other times by a plug, into the reservoir, *o*, where it is washed three times repeatedly by agitation with water and subsidence. The first washings are pumped into the dissolving tun, *A*. In this way the process is continued almost without interruption, excepting whilst the carbonate is depositing in *ff*, and during its discharge into the tank, *o*. After the washing, the product is dried and treated in all respects like that obtained by the Dutch process.

It has been suggested to dispense with the mechanical agitators employed in the dissolving tun above described, by substituting cylinders in which the litharge should be inclosed, and to allow the solution of neutral acetate to percolate them, almost in the same way that syrup is made to pass through the filters in sugar-refining.

PATENT PROCESSES.—Various patents have been obtained in England for the manufacture of white lead, mostly on the principle of THENARD.

One of these, taken out by Messrs. GOSSAGE and BENSON, was put in practice at West Bromwich, near Birmingham. In the establishment constructed for the occasion, the work of conversion was carried on in a large longitudinal trough, by mixing a small quantity of a neutral acetate of lead solution with moistened litharge by means of a travelling wheel, and, at the same time, transmitting heated carbonic acid over the mixture. The carbonic acid was in this case obtained from coke, and the white lead, when fully carbonated in the trough, wasedulcorated, ground in the usual way, dried, and subsequently mixed with the oil for the purposes of the painter. It is said that forty tons of white lead weekly were manufactured by this method, although for some time the establishment has been discontinued.

Another patent was taken out by Messrs. BUTTON and DYER for a process resembling THENARD'S; only that instead of a neutral acetate of lead being the renewing agent, a neutral nitrate was proposed. Both the neutral solution and the litharge were directed to be mixed and agitated together in a tub, the contents of which were retained at a boiling heat by means of steam passing up through the semifluid mass from a coil of pipe in the bottom. Carbonic acid was also

passed into the liquid to decompose the basic nitrate of lead oxide, and precipitate therefrom two equivalents of its base in the form of carbonate of lead. In this, as in the foregoing, the carbonic acid was directed to be obtained from the combustion of coke.

In 1833, a patent was obtained by JEAN BAPTISTE CONSTANTINE TORASSA for the preparation of white lead directly from the metal, simply through the agency of air, water, and carbonic acid. For this purpose the metal was granulated as in the manufacture of shot, and the grains agitated together with water in barrels; the lead dust produced during this abrasion was exposed afterwards to the air for oxidation and carbonisation. This method was tried at Chelsea some years ago by a joint-stock company, who, it is said, expended a hundred thousand pounds in erecting a factory for this process; but it has not answered the expectations entertained of it by the shareholders.

Another patent of a similar nature was taken out by WALKER WOOD in 1834; and in 1847, M. CANNEL specified the following method:—He constructs a hexagonal or octagonal cylinder of lead, six feet and a half long, and fifteen and a half inches or less in diameter, the lead to have a thickness of two to three inches. He incloses this cylinder in a frame made of rod-iron, to one end of which a crank is attached, and places the whole on a stand in such a way as to be readily put in rotation. By means of an opening, or bung-hole, in the middle of the cylinder, the materials, consisting of about two hundredweight of granulated lead and six and a half gallons of water, are introduced. At the other end of the cylinder there is also an orifice in the axis of the cylinder from one inch to an inch and a half in diameter, through which an elastic tube, connected with a bellows or other blowing machine, is passed, till it reaches about the middle of the cylinder.

In the machine thus constructed the materials, as specified above, are put, the bung-hole closed, and the whole rotated at the rate of forty-five or fifty revolutions per minute; this mode of operation is continued during five hours, when two-thirds of the lead will be found abraded to an impalpable powder, but retaining its metallic lustre. On opening the lateral orifice, this fine powder undergoes rapid oxidation, and a hydrate of oxide of lead is obtained. Finally, if the chamber where the blowing apparatus is fixed be charged with carbonic acid from the burning of charcoal, *et cetera*, on putting it in operation, a stream of this gas will be forced into the cylinder, and the oxide of lead will pass to the state of carbonate.

The mixture is then discharged from the cylinder into a tub beneath the lateral opening, and agitated with water, during which the metallic powder falls to the bottom, and the lead salt acquires a remarkable degree of whiteness. As it is somewhat difficult to separate the small metallic portions, M. CANNEL advises to agitate the mixture in a tub having openings at different levels, through which the carbonate may be drawn away. The pasty mass is thrown on cloth filters, and after the water has drained, pressed more or less; then dried in the stove-room and ground with oil in the ordinary way. To facilitate the oxidation in the cylinder, nitric acid may be added to the water to the

extent of one and a half to two pounds; or a saturated solution of neutral nitrate of lead may be substituted. The advantages of this method are, according to M. CANNEL, simplicity of operation, a larger product, saving of manual labor, and less chance of loss.

In 1841, Mr. H. L. PATTISON obtained a patent for the manufacture of white lead by means of bicarbonate of magnesia and chloride of lead. The magnesian salt is prepared by calcining coarsely-ground dolomite—magnesian limestone—at a red heat, by which the entire of the carbonate of magnesia is decomposed, whilst the carbonate of lime present is only very slightly affected. This powder is afterwards suspended in water within a cylinder of iron, furnished with an agitating shaft, safety valves, induction and eduction pipes, and carbonic acid is forced into it by a pump as long as absorption of the gas ensues. On drawing off the contents of the cylinder, a solution is obtained marking 5·6° Twaddell, and containing sixteen hundred grains of the carbonated salts per imperial gallon. A saturated solution of chloride of lead in water is now prepared, and which at a temperature of 50° to 60° will indicate a density of 1·008; consisting of one part of the lead salt dissolved in one hundred and twenty-six of water. Both solutions are then mixed together as rapidly as possible, taking the precaution to have the magnesian solution in excess. The quantities of each solution which ought to be taken must be determined by a trial test on the small scale. On running the two liquids in the proper proportions in two converging streams into a tank, from which the mixture issues by a tap-hole at the bottom into a settling vat, carbonate of lead mixed with a little basic chloride of lead, will be found in the latter after subsidence. To separate the chloride of lead which exists in it to the extent of one or two per cent., the dried compound is ground in a horizontal mill with a concentrated solution of potassa or soda, and letting the pasty mass stand for a day or two, after which the chloride of the alkali metal is washed out, and a compound is left, which, when dried and properly prepared, is represented to be equal to the best *ceruse* in body and purity.

Mr. LOTHAM's patent, sealed in the beginning of 1847, directs that a six-foot cubic apartment should be provided, in which by upright posts and horizontal wooden rods, the sheets of lead should be conveniently supported without touching one another; the sheets to be two feet long, one in breadth, and one-sixteenth of an inch thick. Beneath the floor should be a flue in connection with a furnace, by which the chamber may be heated to a temperature from 72° to 96° Fahr. On the floor is placed a tub in which are eight pecks of malt, two pounds of sugar, six pints of yeast, and twelve gallons of water. This mixture ferments, and ultimately gets mouldy, when it is drawn off into other vessels, in which it is mixed with two gallons of vinegar and heated by steam, after which it is gradually introduced by pipes to the floor of the chamber. It gives off acetic acid, which corrodes the lead, and the carbonic acid from the fermentation converts the oxide into white lead.

TOURMENTIN patented a process in 1847, for manu-

facturing white lead from the chloride of this metal. The latter compound was to be produced by grinding litharge, chloride of sodium, and water together, employing an excess of the litharge; basic chloride of lead was thus obtained, which, upon treatment with a stream of carbonic acid, yielded a precipitate of carbonate of lead, leaving a neutral chloride of lead in the solution. By drawing off the latter, and boiling it with chalk till, on testing with sulphide of hydrogen, the clear liquid gave no blackening, the portion in the solution was precipitated as carbonate, and afterwards separated from the lime salt by washing.

RICHARDSON prepares white lead by taking the crystals obtained in the desilverizing of ordinary lead by PATTISON's process, or metal otherwise reduced, and mixing with it from one to one and a half per cent. of vinegar, or a proportionate quantity of nitric acid, acetate or nitrate of lead diluted with water; and after turning the mixture over repeatedly, placing from twenty to thirty hundredweight of the mixture upon the shelves of a chamber lined with lead, slate, or stone. Heated air is admitted by a pipe furnished with a stop-cock, also steam to retain the compound moist, and carbonic acid from any convenient generator. Provided the temperature be retained at 96°, or thereabouts, the conversion of the lead will be effected in ten days or a fortnight. The salified mass is then removed and ground, then agitated with water, and any metal which separates returned to the chamber with fresh acid.

DISBROW RODGERS in a patent sealed in August, 1849, gives a process which consists in suspending sheets of lead on frames of wood in a steam-heated chamber, and thus exposing them to the joint action of acetic acid, carbonic acid, and steam; the acetic acid being derived from troughs of pyrolygneous acid into which steam pipes pass, or from other sources placed on the floor, and the carbonic acid from fermenting mixtures of yeast, sugar, malt, and water, also contained in troughs placed upon or sunk in the floor. Of course one condition of the success of the operation is, that the chamber be air-tight or nearly so, and a temperature of 80° maintained by the introduction of steam for a short period several times in the day. Every forty-eight hours this compartment must be entered, to renew the fermenting and acid liquors during the time that the process lasts, which is usually twelve days.

In 1853, M. CHENOT laid before the French Academy a process for the manufacture of white lead, which according to that gentleman offers facilities for the production of this article, that render it much more eligible than the established method. It consists essentially in the treatment of lead ores by metallic sponges, whereby a leaden sponge is precipitated, and this is subsequently exposed to the air and moisture, easily oxidises, and becomes converted into white lead. Pure galena, such as is known as *alquifoux*, is the ore employed by him; it is transformed into sulphate of lead by very careful roasting in a reverberatory furnace, the heat and working during the time being so controlled, that the matter does not enter into fusion. When the whole of the lead has thus been converted into sulphate, the product is mixed with iron or zinc sponges in a suitable vessel which contains an acidulous water, and is heated by steam, or

some other mode of artificial heating. The whole is thus left during a period extending to ten or fifteen days, with occasional stirring, at the end of which period the lead will be found at the bottom of the vessel, and a solution of the precipitating agent in the form of sulphate.

By decantation the supernatant liquor may be removed, when the residue is treated with a dilute sulphuric acid, to remove any particles of iron or zinc that may be present with the lead; but the solution, so produced, may be employed to moisten the materials of the next precipitation. After this liquor is drawn off, the residue is washed well with water till neither zinc nor iron, which of them soever may be employed, is detected in the washings; after which it is to be laid on trellises, in layers of .3937 to .7974 of an inch thick, and moistened. It will be changed in a fortnight or a month to a magnificent ceruse, of a beautiful white and velvety appearance. The lead sponge oxidised at a temperature of 392° gives the same results, and the tones of these compounds are superior to those now made, and are very powerful in their action. M. CHENOT, in the above communication, assures the Academy, that no manufacture can possibly be safer in a sanitary view than that of white lead, according to the foregoing process; that the product is perfect, and exerts a powerful action on fatty bodies, whilst, at the same time, the compounds are obtained with extraordinary simplicity and precision, without the expenditure of manual labor consequent on the other methods.

Theory of the formation of White Lead.—For a long time, although some general opinions were advanced with regard to the formation of white lead in the fermenting stacks, by the agency of acetic acid, air, and carbonic acid; still, till within a recent period, there existed a degree of uncertainty as to what the real changes were, in the minds and writings of scientific men. It has been already stated in general terms, that there is formed in the *stack* a basic acetate of lead which suffers decomposition, from the assimilation of the basic oxide by carbonic acid, leaving a neutral acetate to operate further upon the metal. Recent experiments have shown, however, that the substance produced is also a basic compound of neutral carbonate of lead, with a hydrated oxide of the metal, and the question was suggested—Why does not the carbonic acid present react upon the free oxide of the carbonate, as well as upon that of the basic acetate which is generated? It would seem

at first sight that such a result would be the most likely one to be produced, more especially since the basic acetate must necessarily be in contact with the metal, and that the gas must traverse the exterior coating of carbonate to influence it in any way. Knowing that white lead is capable of assimilating a larger percentage of carbonic acid than that which it yields, it is natural to infer, that instead of a basic compound, a neutral one of oxide of lead and carbonic acid should be obtained. Theory in this case would be in direct opposition to practice, and egregiously erroneous also. BARRESWILL has lately shown, however, that when anhydrous neutral carbonate of lead is added to a solution of the basic acetate of this metal, white lead of the composition above stated separates; and hence the first portions of the acetate which are decomposed by the carbonic acid, although such be a neutral carbonate, are thus changed by contact with an excess of the basic acetate into the ordinary white lead. It follows from this, that if there is a deficiency of the basic acetate of lead, the chief part of the corroded metal will be converted into neutral carbonate of lead, and that its qualities as a paint will be materially depreciated on account of the molecular structure of that body. This inference is strengthened by the experience of white lead manufacturers. There is little doubt of this being the true change which occurs; yet URE believed the metamorphosis impossible, from the fact that acetic acid is regarded by him as exercising a more powerful combination than any which carbonic acid is capable of exerting. It should be remembered, however, that in many chemical reactions the existing state of the elements frequently modifies the changes which in other respects they give rise to, more especially when the substances are capable, like lead, of producing compounds, the constituents of which are held together by a very weak affinity; and although carbonic acid alone does not expel acetic acid from its combinations with one equivalent of lead in the presence of water, the heat of the stack may be conducive to cause its expulsion in the presence of carbonic acid. URE assumed, that in the action of the acetic acid upon the lead a sexbasic compound is produced, which undergoes a kind of *eremacausis* that determines the conversion of the acetic acid into carbonic acid and water, the former of which is proportionate to the quantity of this gas combined with the ordinary white lead.

No reliable experiments, however, are extant to show whether any such combustion of the acetic acid takes place, or that the sexbasic compound of lead is produced in the stack.

It was also supposed that the oxidation of the metal did not take place through the medium of the oxygen of air, the stack being thought too compact for the due circulation of the volume necessary for this purpose; but rather that the acetic acid was the means of effecting, first the oxidation, and secondly, the carbonization; the extra carbon and hydrogen of the deoxidised acid being

evolved as a peculiar etherous combination. It is needless to say that this view was erroneous, for, in the first instance, the quantity of acetic acid employed bears no proportion to what would be necessary were the manufacture to proceed in conformity with these changes; besides, HOCHSTETTER and others have proved, that where atmospheric air is excluded, carbonic and acetic acids are insufficient to convert the metallic lead into the carbonate to the extent which occurs in the system commonly adopted.

Composition of White Lead.—From multiplied ana-

lyses, by several well-known chemists, of the English and foreign white lead of various factories, it appears that its composition almost invariably is, two equivalents of the protocarbonate of lead united with one of the hydrated oxide, and agreeing with the formula $2(\text{Pb O}, \text{CO}_2) \text{ Pb O}, \text{HO}$.

MULDER, in his researches upon white lead, arrived at these results; so also did HOCHSTETTER; and latterly the examinations of LINK and PHILLIPS corroborate the same. The precipitated compound, such as that prepared at Clichy, has a similar composition, owing to the fact expressed in the preceding, that by the reaction of carbonic acid or neutral carbonate of lead upon the basic acetate, a precipitate of analogous composition to the above falls. If the transmission of the carbonic acid be continued till the menstruum indicates the evanescent acid reaction peculiar to it, the whole of the lead will be carbonated, and a compound obtained, much less adapted for the painter than if the operation were not pushed so far. Previous to the investigations above alluded to, it was supposed that the Clichy white was a simple carbonate, and that the disparity of effect manifested by it, compared to the Dutch kinds, was owing to this; but PAYEN and URE proved by strict examinations, that the former variety when obtained in the cold from moderately dilute solutions, was composed of irregular plates finely divided, but the superposition of which did not offer the same degree of opacity as an equal weight of the Dutch white. It would appear, however, that when the compound is thrown down from hot concentrated solutions of the basic salt, the crystalline structure is considerably diminished, and the product is more opaque and spreads better under the brush of the painter.

Occasionally a species of white lead is produced by the Dutch method, which yields on analysis numbers corresponding to the formula $3(\text{Pb O}, \text{CO}_2) \text{ Pb O}, \text{HO}$; that is, three equivalents of carbonate to one of oxide of lead. It has a loose friable texture when drawn from the heights, quite distinct from the hard crates of white lead obtained when the metal is almost wholly converted; and is invariably the result of defective corrosion of the metal. This kind of white lead does not cover so well as the hard lead.

ANALYSIS OF WHITE LEAD.—The analysis of white lead as taken from the metal or from the drying-house is very simple, but becomes more difficult in the form of paint, for then not only do the oleaginous matters present inconveniences, but generally speaking various other mixtures, such as sulphate and carbonate of baryta, sulphate of lead, antimonial compounds, *et cetera*, are incorporated. It suffices, when the compound is dry and uncombined with oil, to desiccate a known portion of the average sample, reduced to a fine powder, in a water-bath as long as it ceases to lose weight, and note the loss thus sustained. The crucible may then be exposed to a dull red heat, for the purpose of expelling the carbonic acid; weighing as in determining the wa-

ter, and when this is done, setting down the loss before heating in the flame, and after. To insure that the whole of the carbonic acid is expelled, two weighings after prolonging the heat should correspond. Pure white lead yields:—

	Centesimally.
Oxide of lead,.....	86.377
Carbonic acid,.....	11.310
Water,.....	2.313
	100.000

Now if the percentage of water and carbonic acid in the sample examined coincide with these numbers, it will be evident that the sample is pure; but should the amount of carbonic acid found be greater than that given, it is a sign the preparation, though not adulterated, is still of inferior quality, since the proportion of the carbonate is increased in relation to the oxide present, and consequently if used as a paint, it loses in body through this constitution. Since a difference of 0.7 per cent. of carbonic over the foregoing numbers in the analysis, indicate that another equivalent of carbonate of lead is associated with the same weight of hydrated oxide, it is evident that the utmost care must be exercised in making a true estimation of the carbonic acid and water. If the latter should not be wholly expelled before experimenting for the carbonic acid, it is plain that an error would be made in the results, since any residuary moisture will be estimated as carbonic acid.

PHILLIPS has devised a plan by which all or most of the liabilities to error are obviated; but to manage the operation with success requires some skill and prac-

Fig. 338.

tice. He takes an apparatus fitted up as represented in Fig. 338, in which A is an aspirator connected with the chloride of calcium tube, B; this in turn is joined with the potassa liquor bulbs, C, the second chloride of calcium retainer, D, the tube, E, into which the sample to be analyzed is put, and the U-tube, F, holding, in one limb, pieces of pumice moistened with concentrated sulphuric acid, and in the other, partly fragments of fused chloride of calcium, and solid potassa. All the connections are made by means of corks, quill-tubing, and caoutchouc connectors. About twenty grains of the sample being carefully introduced into the bulb of the tube, E, and united at both ends, the flame of the lamp is cautiously applied to it, and at the same time a gentle stream of air drawn through, by turning the tap of the aspirator. As soon as the moisture is supposed to be expelled, the heat is increased, and the carbonic acid becomes thus liberated, but retained in the bulb apparatus, C. After the carbonic acid ceases to be emitted, and the residue in the bulb presents the well-known appearance of litharge, the parts, B, C, and

D, are quickly detached, and weighed. The acquired weight of B and C, combined, will indicate the carbonic acid in the sample, whilst that of D will show the water present. The oxide of lead is estimated in this way indirectly, since it constitutes the difference. When, however, impurities exist, this will not answer, and therefore, the weight of the impurity must be determined, or that of the oxide of lead combined with carbonic acid, as well as that associated with it as hydrate. If the impurity be of an insoluble nature, such as sulphate of lead or baryta, the carbonate must be dissolved out by acetic acid, the residue washed, dried, ignited, and weighed. Should the insoluble portion be a mixture of the sulphates of lead and baryta, and that the quantities of each are to be found, the most expeditious course is to heat the contents of the crucible with sulphide of potassium or of sodium, keeping the vessel covered. After a quarter of an hour's heating, the flame may be removed, the contents of the vessel washed out with hot water, filtered to remove the excess of alkali, and the residue treated with dilute nitric acid. Sulphide of lead produced in the preceding operation is thus dissolved, and after filtering off the liquid and washing the residue, the metallic oxide may be removed from it in the form of sulphate, by adding sulphuric acid in excess, and diluting. The latter precipitate is then to be filtered, washed with a very attenuated sulphuric acid, dried, ignited, and weighed. If from the entire residue the amount of sulphate of lead obtained in this way is deducted, the difference will be the barytic compound used. When carbonates of baryta or lime are added, these compounds do not part with their acid at the same temperature at which the white lead yields its carbonic acid, so that the estimation of the loss by heat, managed so as to be barely at a dull redness, will represent the proportion of the valuable compound existing in it. The residue may be examined for carbonic acid in WILLS' apparatus, and its amount will give indirectly the weight of carbonate of lime or baryta present in the sample.

ADULTERATIONS.—All the white lead which is manufactured into paint is more or less sophisticated, and chiefly with barytic compounds. The practice is carried on to such an extent, in some cases, that more than three-fourths of the mineral constituents of the paints are adulterants. This is invariably done at the manufactory, and, unless specially required, the white lead is never ground *per se* with the oil; and, therefore, the various qualities of white lead are in some respects synonymous with the extent of spurious matter incorporated with it. In Belgium there are several kinds—the *Kremser white* being unadulterated, but the others largely so: thus, *Venetian white* is a mixture of heavy spar and the subcarbonate of lead, in equal proportions; *Hamburg white*, of two parts of heavy spar and one of the plumbous compound; and that known as *Dutch white* contains three-fourths of sulphate of baryta. Many of these compounds are mixed with a small quantity of charcoal, indigo, or prussian blue, so that the dead yellowish shade which they present may be enlivened to a brighter hue.

Before leaving the subject it may be stated, that of late years efforts are being made to supersede the

manufacture of carbonate of lead entirely, by substituting for it other compounds, which, when mixed with oil, give a white paint. Of these, the principal are oxide of zinc, the teroxide of antimony, sulphate of baryta, *et cetera*; but the oxide of zinc comes nearer to the true substitute than the others: for this enters into a combination with the oil, just as the oxide in the white lead gives rise to an oleate that considerably aids in the extension of the paint on the surface, and causes it to form, at the same time, a perfect coating.

Oxychloride of Lead.—This is a compound lately introduced by Mr. PATTISON, who has obtained a patent for its manufacture. It is described as possessing properties which are superior to those of white lead, inasmuch as it does not so readily blacken with sulphide of hydrogen as the latter body. To prepare it, the patentee dissolves pure chloride of lead in water at the temperature of 212° , in quantities averaging five-sixths of a pound to a cubic foot of liquid. Soda, potassa, lime, or baryta in the caustic or hydrated state, may be employed to precipitate the lead from the solution, but as lime is the cheapest, it is of course preferred.

When lime is the precipitant, a saturated solution of it is made in cold water, in which case a cubic foot of the liquid will contain one-half of the equivalent of the lead contained in the plumbous liquor. If the water employed to prepare this liquor contains soluble sulphates or carbonates, a corresponding quantity of the lead will be precipitated in the form of sulphate or carbonate, and consequently more chloride of lead should be employed than above specified, so that the lime may not be present in excess, in which case it would dull the aspect of the preparation. The solutions being thus prepared, they are suddenly mixed, for which purpose the patentee employs two tumbling-boxes of sixteen cubic feet capacity, and placed over a cistern or tank into which the two boxes, when full, are inverted, and cause the two liquids to mix instantaneously. Basic chloride of lead having the composition represented by the equation $Pb\ Cl, PbO, HO$, that is, an equivalent of chloride and of oxide of lead, falls; and after complete subsidence, the clear supernatant liquor which contains chloride of calcium and a trace of lead, is siphoned off to another tank, and there mixed with a further quantity of lime-water. Should any of the lead salt escape decomposition, it is here converted into the hydrate which falls to the bottom of the tank, and may be recovered. It would appear that when the oxychloride of lead is employed as a paint, the oxide contained in it gives rise to an oleate of lead, and, in consequence of this saponaceous matter, is capable of spreading over an extended surface like ceruse. URE, however, found that water removes the chloride of lead from the paint compounded of this article, and, consequently, that it is not so effectual as the carbonate or white lead.

Physiological Effects of Lead and its Compounds.—With the exception of one or two of the most insoluble compounds of lead, all the others are known to have very active poisonous properties. The sulphide of lead, the sulphate, and sulphite, if possessed of such, are not,

however, so virulent as those salts of the metal which are soluble in water, or in dilute acids. It is to be remarked, that miners of galena are seldom, if ever, incapacitated by any derangement to their health arising from saturnine poisoning; when, however, they chance to be removed to the smelting establishments, after a while occasional indications of the physiological effects of lead on the system are observed. Dr. SCOFFERN, when, a few years ago, advocating the use of acetate of lead for the purification of saccharine juices, affirmed the innocuousness of sulphite of lead, owing to its insolubility; but no well-confirmed proofs exist of the truth of the assertion.

Lead, *per se*, is supposed to have no effects on animals; nevertheless its ready solution by the fluids and juices in the stomach, brings it into a state in which it is rapidly absorbed into the system, and thus becomes poisonous. Therapeutically considered, the preparations of lead have sedative and astringent properties, since they diminish the volume and frequency of the pulse, and reduce the secretive functions. Thus, when it is employed for some time, the arteries become reduced in size and activity, as indicated by the smallness and slowness of the pulse; hence its use in checking hæmorrhage, whether natural or artificial, and in reducing the temperature of the body. These characteristic effects extend to the secreting and exhaling vessels, as may be known from the dryness of the mouth and throat, the thirst, *et cetera*, which succeed its absorption. If present in quantities, other very decided indications are observed, such as the well-known leaden discoloration of the gums, of the buccal mucous membrane, and of the teeth; the peculiar taste and odor of the breath; the lead jaundice, and ultimately general emaciation. The coloration of the gums, membrane, and teeth is recognized by a leaden or slate-blue line from one-twentieth to one-sixth of an inch in breadth, which forms on the margin of the gums, nearest to the incisors in either jaw, whilst the rest of the gums appear of a bluish-red tint; the membrane lining, the gums, and cheeks are also of a bluish color, and the lower part or neck of the teeth are stained brownish. It would appear that these various shades of color are occasioned by sulphide of lead, produced doubtless by the traces of sulphocyanogen which is known to exist in the saliva flowing from the glands of the mouth. Saturnine breath is known only to those who are affected by lead through the respiratory organs, such as persons engaged in the manufacture of the compounds of this metal already referred to. Emaciation, which is another of the most marked of the primary effects of lead, shows itself more evidently in the face of the patient, giving to it a careworn, wrinkled, and aged appearance. When the lead accumulates in larger proportions, whether by accident or long-continued use of small quantities of plumbous compounds, it gives rise to various diseases known as *lead colic*, *anthralgia*, *paralysis*, and that which is characterized as *encephalopathy*, and which manifests itself by different morbid phenomena, such as delirium, coma, and convulsions, with or without loss of one or more of the senses. Physicians have observed, that patients are liable to several of these at once, although the most frequent of them is the lead colic.

Lead Colic, the symptoms and characteristics of which need not be entered upon here, is generally accompanied by the blue coloration of the gum, and this enables the practitioner to define the variety of the complaint.

Lead Anthralgy. It shows itself by pains in the limb. These usually become acute by paroxysms, are diminished by pressure, increased by motion, and are accompanied by cramps and hardness of the painful parts. In this case also, the blue line of the gums shows whence the disease springs.

Lead or Saturnine Paralysis. This ailment is characterized by the loss of voluntary movement of the parts affected, owing to the want of the power of contracting the muscular fibres of such parts. It is more frequently observed in the upper extremities, although the lower are also liable to be affected by it. The extensor muscles are more frequently diseased than the flexor, so that it manifests itself most frequently in the hands, arms, and legs. Pain is experienced frequently in the affected parts, and sometimes also in the region of the spine. Generally, lead paralysis, succeeds the saturnine colic, although it may come on whilst the patient is suffering from the latter. This disease is likewise distinguished from others of a similar nature, by the blue line in the gums which is very marked at its commencement.

In all these forms of disease as well as the cerebral ailments classed under *saturnine encephalopathy*, it is the general opinion, that the greatest effects are produced from local causes, arising from the inert compounds which the metallic base forms with the albumen, *et cetera*, of the tissues and parts which absorb it. At first sight it would seem, since such a combination is capable of being produced, that absorption could not take place; but though slow in this respect, when compared with other substances, experience has demonstrated its presence in the brain, spinal cord, and other parts of the body, to which access could not be made, excepting from the respiratory organs or the stomach. Some persons are so susceptible to poisoning influences, that the vapor from lead paint even has been stated to enter the system, and produce symptoms of a most alarming character, as recently noticed by Dr. WATSON, the eminent physician of London.

Poisoning by Lead.—When compounds of lead are taken in such quantities as to be destructive to life, the physical indications which are observed differ with the form of combination of the metallic oxide; thus, for instance, the acetate of lead acts as an irritant, but the carbonate—white lead—has no such action, or at best only a very indecisive one; the same may be observed of the oxide and other compounds of lead, especially those of limited solubility. The general physiological effects already mentioned, are guides which do not fail to point out the cause when death or violent attacks through the poisonous action of lead follows.

Antidotes.—Two classes of agents are known which lessen or destroy the poisonous effects of lead; these are sulphide of hydrogen and the soluble metallic sulphides, and sulphuric acid and the soluble sulphates. With the first class, black sulphide of lead is immediately formed, and as this body is almost inert, if not innocuous, the further deleterious action of the lead salt is

averted, as soon as the metallic base is changed to the form of sulphide. In a similar way the sulphuric acid and the sulphates act, only that a white sulphate of lead is generated in this case. It is doubtful, however, whether the sulphates and sulphuric acid operate as an efficient antidote, since it is probable that portions of this salt are dissolved by the chlorides of the alkali-metals, which are always present in the stomach, and likewise by the alkaline acetate, which is formed when a soluble sulphate is administered in cases of this saturnine poisoning. For the most part the first class antidotes are applied topically, in the form of a bath, and the second internally, in that of draught, *et cetera*; the former decompose any lead which may be on the skin, and convert it into sulphide, thus preventing its absorption; and the latter check the progress of the poison interiorly.

Acute lead poisonings are rarely observed, excepting they arise from inadvertence or accident, either purely so or malicious; but the first stages of slow poisonings are very frequent, and well known to most of the general medical practitioners in every large town, as well as in the rural districts. The source is almost invariably found to be the water employed for domestic purposes, the lengthened use of which causes a depression of spirits, emaciation, and, finally, colic and paralysis. Several cases of this description have come under the notice of the Editor, wherein whole families were affected, and though the leaden indications in the gums were undiscerned—as their medical attendant in many of them appeared baffled by the continued and frequent complaints—still, carefully conducted analyses proved that lead was the undermining agent. Iron-glazed pipes and pumps, with slate or cemented cisterns, were recommended for adoption, and with a very marked effect, the health of the individuals being completely restored. Many waters containing lead are preserved as by an antidote from effecting any injury to the consumer, and are consequently quite safe for consumption. The substances that react thus are the sulphates, phosphates, and carbonates of the alkalies, and also the sulphates, carbonates, *et cetera*, of the alkaline earths; in fact any neutral salt, the acid of which is capable of combining with lead or its oxide, and of constituting an insoluble compound, has this effect. It is owing to the presence of one or more of these, that mineral or spring water, though passed through lead pipes and retained in cisterns of that metal, remains for the most part unimpregnated with lead. So small a quantity as three or four grains of a sulphate or a phosphate in a water, prevents after some time the corrosion of the metal; carbonates have a similarly marked effect, more especially the soluble bicarbonate of the alkaline earths, since an oxycarbonate of lead is formed, which is one of the most insoluble combinations of lead, only one part being taken up by four million parts of water. It must, however, be remarked that these salts do not protect the lead from the solvent action of waters which contain *nitric* or *nitrous* acids in solution. These two acids are products of the decomposition of animal matter, and any water containing them will infallibly act upon lead; and, consequently, it would be highly dangerous to pass such a water through leaden pipes, or to store it in leaden

cisterns. All of these insoluble precipitates, after accumulating for some time on the sides of the cistern and on the interior of the pipe, form a solid coating, which in a measure isolates the metal from contact with the water, and, consequently it is protected, and the water remains good and wholesome. Chloride of sodium acts also as an anticorrosive substance to the water, but its effects are less certain than those of the compounds above referred to, since the chloride of lead is much more soluble than either the sulphate, phosphate, carbonate, or similar salts. As it frequently occurs, however, that in spring waters there are appreciable quantities of nitrates, and even free nitrous and nitric acid, as in a water from the private well in the neighborhood of Birkenhead examined by the Editor; the action of such waters upon lead becomes exceedingly marked, and not unfrequently do they give notable indications of lead being in solution after some time, even though they contain sulphates. In these cases the active solvent agent is still left in the water, and continues to act upon the metal, even after the entire sulphuric acid present has combined with the oxide of lead dissolved. Water, therefore, which retains nitric acid either in the free state or combined, whether it be mineral or catchment water, is not so safe for storage in leaden cisterns. In like manner, the water which retains decomposing, organic, nitrogenous matters in solution or suspension, is unsafe so far as regards the action on lead; for as stated above, the transformation of the elements of such by the *eremacausis* which they undergo, tends to produce, first ammonia, and by a further process of oxidation, nitrous or nitric acid, and at the completion of this change their corrosive action becomes very remarkable—so much so, indeed, as to cause the solution of several grains of lead per gallon. Besides the fact, that waters containing organic decomposing matters are in themselves unhealthy, their subsequent effect upon lead renders them doubly so.

MEDLOCK has latterly patented a method, whereby the nitrates which exert such a powerful action upon lead are removed, together with the organic matter, if the latter be not present in great excess. It consists in suspending coils of iron wire or pieces of sheet-iron in the water, and after a stated period filtering off the deposit which forms. By this means the nitric acid is decomposed by the iron, which is transformed into sesquioxide and falls to the bottom, whilst nitrous gas is set free and oxidizes the carbonaceous matters, which remain still in the fluid so as to yield carbonic acid and a lower oxide of nitrogen.

From experiments made upon some of the water lately supplied to Liverpool, and which proved itself to be a most eligible subject for examination, from the quantity of organic matter, both animal and vegetal, and nitrates, which it contained, the Editor arrived at very satisfactory conclusions, that the object proposed by the patentee may be completely fulfilled.

Action of Water on Lead.—When water which has been purified by distillation from pure caustic potassa, and kept out of contact with the atmosphere, is poured over clean sheets of lead, and so retained for a considerable period, no solution of the metal will be observed to have taken place, nor will the examination of the water indicate that any of the metal has been taken up. This

will not be the case if a comparative experiment be made with rain-water, however carefully collected, even in the open country; for with this the metallic lustre is soon dulled, and a film of carbonate and of oxide of lead forms on the plates, showing that a chemical action must have occurred; and besides, if the liquid is chemically treated, distinct evidence of the presence of lead in solution is found. The same observation will be made with regard to distilled water and lead, when the vessel containing them is exposed to the air, though not to the extent of the former. In these instances, there is a compound of oxide and carbonic acid corresponding to *white* lead, formed through the intervention of the carbonic acid with which the water—in case of rain-water—is charged, or it absorbs this gas in the experiment with distilled water. If the vessel be freely exposed, portions of this carbonate are dissolved; but independently of this, the carbonic acid which is always imbibed from the air, proves much more effectual for its solution, and, therefore, a considerable part will manifest itself to chemical tests, after some lapse of time. Another agent in rain and other waters, that acts with great rapidity on lead, is *nitrous acid*; and latterly Dr. MEDLOCK has shown, that ammonia, by its transformation into this, is capable of ultimately causing the water in which it is present, if retained in contact with lead, to become poisoned. The annexed equation exhibits the interesting transformation:—

Of course, some of the nitrous acid will be constantly metamorphosed into nitric acid, oxidation continually going on. This chemist affirms that the nitrate of lead produced in contact with the metal, is speedily transformed into the quadribasic *nitrite*, with evolution of binoxide of nitrogen, which, by combining with another equivalent of oxygen, re-forms nitrous acid. The production of the lead salt is thus explained:—

MEDLOCK, *contrary to all preceding views with regard to the action of certain waters on lead*, thus correctly sums up:—

Firstly. The action of any water on lead is entirely due to the presence of *nitrous* and *nitric acid*, resulting primarily from the decomposition of organic matters, and of ammonia contained in the water.

Secondly. Waters deprived of these acids, and of substances capable of producing them, *have no action on lead*, and may be conveyed with perfect safety through leaden pipes, or stored in leaden cisterns. To store or collect water containing a nitrogen acid in cisterns or tanks lined with lead, as is usually done for domestic use, is highly pernicious, since the injuries arising from taking lead into the system, and stated above, may follow. And as no other more convenient means for the storage of water and its conveyance are known, especially in small quantities, the first question

relative to the sanitary value of a water which ought to present itself to municipal or corporate bodies, as well as to private individuals, is, does it exert a solvent action upon lead, or does it contain a nitrogenous acid, or any compound likely to produce one. It is true that water which would dissolve this metal in abundance, and, therefore, be rendered unfit for use, is by the presence of certain mineral ingredients rendered less liable to do mischief.

LEATHER.—*Cuir*, French; *leder*, German.—Leather is the compound which the fibrous matter of the skin of warm-blooded animals forms with various substances of an organic and inorganic nature. It remains in a great measure unaltered under the joint influence of air and moisture; and in this behavior differs considerably from the skin, *per se*, since the latter, if subjected to the action of the forementioned bodies, readily undergoes a species of fermentation that resolves itself into the putrefactive kind, and quickly destroys the integument of the skin.

HISTORICAL NOTICE.—Of the early history of leather little is known; still the meagre allusions met with in old records are sufficient to show that it is of high antiquity. Like many other manufacturing arts of long standing, the preparation of leather from the skins of animals originated with the Oriental people, but of the methods adopted nothing is stated to inform the reader of the present day, beyond the remark that alum was used as a tanning agent by the Saracens.

It is recorded that leather was employed among the Romans, long before they acquired the knowledge necessary for its preparation. In those and subsequent epochs it was in request for sandals and other articles appertaining to dress. In the middle ages, it is stated that several uses were made of this article, both personal and domestic, and although the manufacture must have experienced a corresponding impetus, still the mode of tanning or treating skins at that period is in oblivion. According to FOSBROOKE, the Britons in early times exported the skins of their slain animals, but afterwards learned the methods by which they were converted into leather. This is evidenced by the accounts extant of the large tanning establishments which they had, and which were usually erected on the banks of some rivulet, across which they constructed dams for the purpose of intercepting the water for their use, and frequently to the detriment of a large tract of country, which the water occasionally submerged.

Travellers have related that the conversion of the skins of animals into leather is practised by the aborigines of savage nations. Thus, Sir ROBERT SOUTHWELL describes the methods by which the savage tribes of South America prepare skins to make leather:—

On the skin being taken off the animal, the cerebral matter is extracted from the skull, and both it and the skin are dried in the sun's rays. During the exposure, the skin is kept stretched, so that no shrivelling of the hide takes place. When the hunting season terminates, the dried skins are steeped in water, and the hair detached by the use of an old knife; after this, they are placed in an earthen pot with the powdered brains, and afterwards heated to 95°, or thereabouts. By this

treatment the cerebral matter is converted into a kind of soap, which forms a lather with the water remaining in contact with the skins, and it makes the latter very clean and pliable. After remaining immersed for some time, the skins are taken out and stretched in every direction by means of thongs, and a frame formed of upright stakes and cross-pieces. During the exsiccation upon the frame, they are rubbed with a smooth stone, or hard piece of wood, so as to expel the water and fat from the pores of the hide.

Whether the leather employed by the ancient Hebrews and their contemporaries, and of which girdles, *et cetera*, were made, as stated in the book of Kings, was prepared in a similar manner, is unknown. Whatever methods were pursued, it is evident that the making of skins into leather was a business confined to a few who made it their trade, in the beginning of the Christian era, and that the manufacture has been since progressing slowly. Regarding the choice of materials for tanning, such as the barks of trees and the like, it is unknown whether those now in use were then recognized as possessing the virtue of converting skins into leather, or whether the discovery is due to the tanners of the middle ages. It is certain, however, that the scientific principles of the business were not at all, or at best but very imperfectly understood, before the end of the last and beginning of the present century. The investigations of DEYEUX, SEGUIN, MACBRIDE, PROUST, Sir HUMPHREY DAVY, and several other chemists, explained the nature of the changes which took place, and attributed them to true chemical combinations. These researches, therefore, led the tanners to the comprehension of the scientific principles upon which their operations were based, and likewise opened up new sources of improvement. Since then, however, the progress in this art has been much less marked than that of other branches of trade in which chemistry has been a handmaid; and though numerous experiments have been tried, and many patents granted for new processes and improvements, no very decided advantage has been gained to show that the modern system is superior to that practised prior to their introduction. This is the more unaccountable, considering that the growth of social refinements, and increased wants, as likewise the universal impetus which trade, commerce, and manufactures have received during the last half century, created so great a demand for leather as to render it one of the most important articles of manufacture. This is especially the case in England, where—apart from the consumption of this article in boots and shoes—so much of it has been used in connection with machinery, in the manufacture of carding and other apparatus employed in the cotton trade, for saddlery and carriages, in upholstery, bookbinding, and a variety of other branches which are year by year springing up, that the consumption is almost outstripping the production.

MC'ULLOCH considers that the leather manufacture ranks third or fourth in importance, being inferior in money value to those of cotton, wool, and iron, whilst others are disposed to think that it is quite as important as cotton. A glance at the extent of this branch of trade will show at once how much it has merited the

above rank. MC'ULLOCH estimates the number of persons employed in the tanneries alone as exceeding twenty-eight thousand three hundred; and those engaged in the subsidiary trades to which leather gives rise, such as the currier, boot-maker, saddler, *et cetera*, average two hundred and twenty-five thousand, among whom there is expended annually from seven and a half to eight millions sterling in wages alone. The value of the manufactured goods reaches to no less than nineteen or twenty millions annually.

It is plain, however, that without some very great changes or modifications of the old slow process of tanning, the extensive demands for leather, which may be inferred from the preceding, could not have been met. Such modifications have been introduced more especially during the last fifty years, in which time mechanism has done far more than chemistry to expedite the operations and improve the appearance of leather. The mission of chemistry has hitherto extended little further than discovering tanning agents, and extracting the tanning principle, which, when the hide is prepared by mechanical pressure and other treatment, yields up the tannin more readily than the bark. It is nevertheless a fact, that as the operation has been quickened thus far, the quality of the leather has deteriorated proportionably, and hence when a fine kind of leather is required, recourse must be had to the old methods for its preparation.

Proximate Principles of Leather.—As may be inferred from its nature, leather is formed by the combination of the substance of the skin with any other compound which has the property of rendering it impure, and elastic. Many substances possessing these properties in relation to skins of animals, are known to exist both in the organic and inorganic classes; but the one most generally employed, as well as the most efficient, is tannin. That a firm chemical union of the two bodies, such as that above referred to, exists, is evidenced by the modified form of the materials, and the physical appearance and chemical behavior of leather, when subjected to microscopical and chemical examinations. The principle in the skin esteemed by the tanner is, as will be shown later on, a gelatino-fibrous compound which constitutes the basis of leather; and the combining agent—tannin—partakes of an acid nature, so that, by uniting with the gelatino-fibrous material, the former is, as it were, thereby salified, so that it is no longer subject to the ready putrefactive change which the skin undergoes under the influence of air and moisture. As the gelatino-fibrous principle forms only one of several others in the hide of the animal, so the tannin or tannic acid constitutes only one among many other substances in the sources whence it is extracted. In order to render the comprehension of the scientific nature of the business of the tanner as easy as possible, it will be necessary to dwell somewhat in detail upon the materials which he employs, so as to exhibit their respective nature, and show how they mutually affect one another. And firstly,—

THE SKIN.—Strictly speaking, the skin of animals is composed of two parts, the *corium* or *cutis*, and the *cuticle* or *epidermis*: the former is the portion

which enters into the composition of leather, and forms the true skin, and the latter constitutes the exterior covering in which the fur, wool, or hair of the animal

Fig. 339.

is rooted. Some anatomists, however, distinguish three distinct parts in the skin, namely, the *corium*, the *rete mucosum*, and the *cuticle*. These several parts are illustrated in Figs. 339 and 340, the former showing the position of the hair, and the latter the magnified layers of which the skin is compounded. In both, A represents the epidermis; B, the rete mucosum, in which the roots of the hair are embedded; C, the fibrous tissue of the true skin; and D, the cellular tissue beneath the latter, showing the fat cells,

by him, is that for removing the hair and epidermis, both being useless.

The corium, deprived of the epidermis, is a substance organized of a number of fibres ramifying and intersecting one another in every position; leaving, however, interstices contracting in size as they reach the outer portion, and which are more or less charged with fluid matter that serves to renew the cuticle and keep the skin pliant and moist. On treating the skin with water these matters are removed, and ultimately there remains but the fibrous portion saturated with water. In this state it appears semitransparent, and, if the water be expelled by a gentle heat, it assumes the physical appearance of horn, constituting only about thirty-two and a half to thirty-three per cent. of the raw hide. From WEINHOLT'S researches, it appears that the skin deprived of the epidermis and its subjacent fluid, as also of the mucous membrane and fat on the interior, affords forty-three per cent. of solid matter, yielding—

	Centesimally.
Fibrous matter,	74.42
Uncoagulated albumen,	3.49
Extractive matter—soluble in water; in- soluble in alcohol,	17.44
Extractive matter—soluble in alcohol, ...	2.32
Fatty matter and loss,	2.33
	100.00

a, in Fig. 340, and sweat glands, b, with the follicles, h, through which this secretion passes out to the surface of the skin.

Behavior of the Epidermis and Cutis with reagents.—When the fresh skin is immersed and macerated repeatedly in water, the matter of the cuticle is separated from the fibrous substance of the cutis, not by the solution of the former, but, as it would appear, by dissolving an extractive matter amounting, according to WEINHOLT'S analysis, to about eight and a half per cent., and which is probably to some extent intermediate between the horny matter of the cuticle and the cutis; weak acids also abstract it, but solutions of the alkalies and of many of their salts are more effectual for bringing about the separation, since these agents dissolve it. The epidermis, which is analogous to horn, does not combine with tannin or any other substance by the agency of which leather is produced. Hence it becomes useless to the tanner; and therefore, the first process to which hides and skins are subjected

Digestion in water removes the albumen and extractive matter taken up by this menstruum; in alcohol, the further portion of extract dissolves, and ether separates the fat with which the residue is impregnated. If the corium, deprived of the epidermis, be treated with boiling water, it dissolves, with the exception of a little fat and some nervous filaments; and when the liquid is evaporated slowly, a gelatinous residue is left, which, when the entire skin is operated upon, forms the glue of commerce.—See GLUE, *ante*, Vol. II., page 181.—This effect of the water does not arise, however, from the solution of the gelatin which, as might be supposed, the skin contains, but it modifies the components of the fibrous tissue so as to bring them into this compound. The same property is possessed by acids and alkalies in a more powerful degree, since the change is effected by these agents at the ordinary temperature.

Fibrin, albumen, and their modification, gluten, behave in a remarkable manner towards tannin or tannic acid, and by the transformation of the fibrous matter of the corium during the operations to which the skins are subjected in the tanning into a semi-gelatinous mass, they conjointly produce leather.

TANNING MATERIALS.—The second principal component of leather, such as that manufactured into boots and shoes, *et cetera*, is *tannin* or *tannic acid*, a substance of vegetal origin, and very extensively disseminated in plants and trees. For a long time the agent which gave such virtues to oak bark, in converting prepared skins into leather, was little known, and, consequently, the peculiar relation of the proximate principles of this article could not be understood, notwithstanding that, in the absence of this knowledge, the leather manufactured was sometimes of prime quality. LEWIS was the first who drew attention scientifically to the subject. He observed, during an investigation of the nut-galls,

that they contained a substance which gave a black compound with a sesquisalt of iron and precipitated isinglass. DEYEUX, who also studied the point, noticed this substance, but considered it a peculiar resinous matter. It was not, however, till SEGUIN published the results of his labors, that any definite account of it was given. This chemist showed that the unknown body differed from the acid of galls—gallic acid; that it combined with animal matters, more particularly albumen and gelatin, and formed with them unalterable bodies, the analogues of which constituted the main bulk of leather. Since then, manufacturers have given great attention to this principle in the tanning material, and the consequences are that a greater variety of substances producing tannin, available for making leather, have been discovered, and that considerable expedition in the process has been attained. Although the forementioned chemists, with DAVY, CHEVREUL, PELLETIER, LEGRANGE, GUILLOT, HATCHETT, TROMSDORFF, RICHTER, and PROUST, may be justly said to have given a scientific exposition of tannic acid and its behavior, and likewise pointed out its quantity in those plants that yield it most abundantly—still several more recent investigators have contributed to the stock of information on this subject. According to WAHNLENBERG, tannin exists only in perennial plants, and almost solely in the permanent parts. For example:—1. In the perennial roots of certain annual plants, as the septfoil and bistort or snakeweed. 2. In the bark of the trunks and roots of nearly all perennial trees, especially in the true cortical portion. 3. In the trunk and sap of many trees. 4. In the leaves of perennial plants—in small quantities. 5. In the leaves of different varieties of oak; of the *rhus coriaria*—sumac; of the *arbutus uva ursi*—bearberry; of the *arbutus unedo*—strawberry, *et cetera*, in large proportions. 6. In the capsule of the unripe fruit of the *quercus suber ægilops*—valonia oak; *juglans regia*—walnut; *asculus hippocastranus*—horse-chestnut; and *terminalia chebula*. 7. In the pulp of the fruit of the *punica granatum*—pomegranate; *rosa pimpinellifolia*; *garcinia mangostana*—mangosteen; and in the different species of anona.

Of the principal tanning materials imported into England, the following table exhibits the names, although a considerable quantity of oak bark—*quercus pedunculata*—is obtained in this country:—

Common title.	Botanical name.	Whence imported.
Oak bark,	<i>Quercus pedunculata</i> , . . .	Flanders, <i>et cetera</i> .
Larch bark, . . .	<i>Pinus larix</i> ,	Scotland.
Mimosa bark, . .	<i>Acacia sp.</i> ,	New South Wales.
Babool bark, . .	<i>Acacia arabica</i> ,	Bengal.
Cork-tree bark, .	<i>Quercus suber</i> ,	Laruch, Rabat, <i>et cetera</i> .
Hemlock bark, .	<i>Abies canadensis</i> ,	United States.
Sumach,	<i>Rhus coriaria</i> ,	Sicily.
Valonia,	<i>Quercus ægilops</i> ,	Smyrna, Trieste, Morea.
Divi divi,	<i>Cæsalpinia coriaria</i> , . .	{ Maracaibo, Rio de la Hache, Savanilla.
Myrobalans, . . .	<i>Terminalia sp.</i> ,	Bengal.
Algarobilla, . . .	<i>Prosopis Pallida</i> ,	Valparaiso.
Terra japonica, .	<i>Acacia catechu</i> ,	East Indies.
Cutch,	" " " " " " " " " "	Calcutta, Singapore.
Kassu,	<i>Areca catechu</i> ,	Ceylon.

Besides the foregoing, which are partly well known in the trade, other astringent substances have been brought before the public, to be employed *per se*, as tanning

materials, or with oak bark as an adjunct. These are various extracts from species of the *acacia* tribe: gambier, the extract of the *nuclea gambier*, from Singapore; mangrove bark—*rhizophora mangle*—from Arracan, Malabar, and Singapore; turwar or cassia bark; avaraputtai, Tangada jigota—*cassia auriculata*—from Vazigapatam; saracondraputtai—*cassia fistula*—from Madeira and Tinnevely; saul-tree bark from the Saul forests; pomegranate rind; darunka pucker—*dadima jegota*—from Kemaon and Vizagapatam; dalumka khola from the vicinity of Calcutta; jamoon-bark—*eugenia jambolana*—and pearl-bark, from Cuttack; samak-bark from Singapore; vangay or gum-kino—*pterocarpus dalbergoides*—from Malabar; kino, or astringent extract of the *Buchanania latifolia*, from the district of Chota, Nagpore; majoophul or gall-nuts—*ficus infectoria*—from Nagore, *et cetera*; tamarisk gall—*tamarix indica*—from Bombay and Lahore; several kinds of myrobalans; gaub, the fruit of the *diospyros glutinosa*, from Calcutta; hag-plum tree—*spondias lutea*—abundant on the banks of the river Berbice, and commonly used in British Guinea for tanning; courida bark—*aviceennia nitida*—a tree very common on the Eastern coast of Demerara, *et cetera*.

MORFIT remarks:—1. That tannin is never found to any extent in the interior of the trunk of trees. 2. That it does not exist in poisonous plants, nor in those with a milky or viscid sap. 3. That its proportion is greater in young than in old plants. 4. That the tannin is converted to bitter principle, as the plant increases in age. 5. That it is most abundant in the cortical layers of the bark, and is usually absent altogether in the epidermis. 6. That the proportion of tannin in bark varies with the season, decreasing as the severity of the winter increases; and, 7. That the two extremes of quantity are attained in winter and spring.

These remarks admit of an important practical application with reference to the most suitable time for the barking of trees, *et cetera*. But before discussing this subject, it will be necessary to enter more minutely into the nature of the tanning principle.

TANNIC ACID OR TANNIN.—By examining any of the numerous substances mentioned above, it will be found that they yield a product which is capable of precipitating a solution of gelatin, and also of giving a greenish or bluish-black one, with solutions of sesquisalts of iron. To matter exhibiting this reaction, and having an astringent taste, the title of *tannin* was given, irrespective of whatever difference might be exhibited upon further comparison. Now, many of those bodies, which in common with the true type of tannin—that which is extracted from galls—precipitate gelatin, and so far show that they are eligible for tanning materials, are known to differ in their characteristics; for instance, some possess acid properties, whilst others are devoid of them; and although towards gelatin their reactions are similar, their atomic constitution is widely different. Regarding their effect in converting skin into leather, this dissimilarity is not so very material as when the components of each are compared. A distinction is also made with respect to the physical appearance of the precipitate they afford with a sesquisalt of iron, and by

this all the known tanning materials are divided into two classes. In the first of these are placed gall-nuts and the barks of the several oaks, and the second includes the quinquina, the cachou, gum-kino, pine barks, *et cetera*. The tannin afforded by the first throws down a bluish-black or purple combination, whilst the precipitate afforded by the second is greenish. Experiments have shown that such distinctions are not very marked, since the tannic acid from nut-galls or oak bark, in the presence of an alkali, will occasion a greenish precipitate when added to a sesquisalt of iron, and a bluish or violet compound when acids are present. HATCHETT first observed that many plants contain a carbonaceous principle, which, when acted upon by nitric and sulphuric acids, according to the method of CHEVREUL, yield a substance which, like the tannins of the foregoing barks and fruits, throws down gelatin, and renders it imputrescible. This variety has been designated artificial tannin; but, in the present state of chemical science, it could not be compounded with the natural products. BERZELIUS, GEIGER, WALT, and CAVALLIUS, are of opinion that tannin, from whatever source it may be obtained, is identical, and that the difference of the reactions with the iron salt must be attributed to impurities which are accidentally present. STENHOUSE, in his more recent researches, has shown that such is not the case, but that all those forming precipitates with sesquioxide of iron, varying from the color of that which the tannin of nut-galls affords, must be regarded as a distinct substance, in which case there seems to be an almost endless variety. Even when the iron reactions of some tannins agree, and also appear analogous in other chemical relations, the same chemist states that the composition is frequently diverse. Hence he distinguishes the various kinds of tannin by the source; thus, that obtained from nut-galls he calls from gallotannic acid; from oak bark, quercitannic acid; fustic—*moris tinctoria*—moritannic acid, and the like.

Preparation of Tannic Acid.—It is very difficult to prepare tannic acid of absolute purity, so much so that none of the methods in use for its extraction can afford a product free from foreign matters. When extracting tannin on the small scale, nut-galls are selected, as they yield the largest product. A quantity of these is dried and reduced to powder, and subsequently exhausted of the tannin with water by moistening with this liquid, then subjecting to pressure. The extract thus obtained, if employed with fresh portions of the powdered galls successively, becomes highly saturated with tannic acid. Filtration cannot of itself clarify the opaque inspissated liquid; but on mixing it with a little dilute sulphuric acid, and agitating, a precipitate of the suspended matter forms, and may be removed by filtering it through linen or paper. To the clarified liquid a solution of carbonate of potassa is cautiously added, till it almost ceases to deposit any matter from the menstruum. The crude tannate of potassa thus obtained is separated from the liquid, washed with ice-cold water, or with water at as low a temperature as possible, and dissolved in boiling dilute acetic acid. On cooling the latter, a brownish deposit containing acetic acid parts from it, and must be removed by passing the liquid through the filter.

A solution of subacetate of lead is now added to the filtrate, and the resulting tannate of lead, removed and washed thoroughly, then disseminated in water, and a current of sulphide of hydrogen passed through till the whole of the metallic base is converted into sulphide. By evaporating the liquid after the separation of the sulphide of lead in the hollow of a flask, containing some carbonate of potassa, the tannin is procured in the form of gummy transparent scales of a yellowish color. In this state, however, the tannin is still impregnated with a little gallic acid and brownish matter, which may be removed by treating the powdered substance with successive portions of ether. The tannic acid is thus left in combination with the brownish matter; but by repetition of the process, this impurity, as well as the gallic acid, is dissolved out, and the tannic acid remains nearly colorless.

This substance may likewise be prepared by treating the clarified extract of gall-nuts, as above directed, with ammonia till almost neutralized, and to the menstruum chloride of barium is added till it ceases to throw down a precipitate. The flask is then filled with water, and allowed to repose till the whole of the tannate of baryta has deposited. Any gallic acid which may have been formed, remains combined with the base in the supernatant liquid, and may, consequently, be removed by decantation and washing. During these operations, a small portion becomes decomposed and colors the baryta salt greyish; on treating the latter with acetic acid, however, this impurity remains, whilst the tannate of baryta is dissolved. To the liquid thus obtained, subacetate of lead is added, and the plumbous salt proceeded with, as directed above.

When the substance is to be obtained in its greatest state of purity, recourse must be had to the process known as that of PELOUZE, but which was first broached by LAUBERT. The latter chemist directed the formation of an extract of sixty grains of powdered nut-galls in one hundred and twenty of ether, the digestion to be continued during twenty-four hours, after which the ethereal extract was to be filtered and evaporated. PELOUZE followed the foregoing method in principle by employing the apparatus of ROBIQUET and BOUTRON, as used for the preparation of amygdalin. Fig. 341 represents this digester. It is an elongated glass vessel, A

Fig. 341.

having an orifice at the top, which is fitted with a ground-glass stopper, and contracting towards the other extremity, which fits tightly into the neck of a bottle or matrass, B, which receives the extract. Sometimes the lower bottle has a second tubular opening for the purpose of receiving a cork furnished with a tube, to which a connector, C, of caoutchouc is appended, the other end being attached to a similar tube fitted in cork which closes the top orifice. This adaptation causes the filtration to take place much more readily, whilst it prevents contact with any further quantity of air beyond what is contained in the apparatus. The further process is such as already detailed.—See Vol. I. page 581. By careful evaporation—the better if under the exhausted receiver—the tannic acid is obtained in the form of a spongy iridescent, uncrystallizable mass, having a light straw-yellow color. It may be washed with repeated quantities of ether to remove any remaining gallic acid, after which treatment it may be desiccated as previously stated. So prepared, tannic acid is in its purest known state; but as sometimes it results almost colorless, doubtless it is not free from impregnations arising from decomposed tannin—apothema—or some other matter.

Another modification of the method just detailed was introduced by DOMINÉ, and offers the advantage of yielding a larger product, while it admits also of being applied on the large scale for the purposes of the manufacturer. He places the powdered galls in a damp cellar for several days, during which they absorb moisture; the powder is next transferred to a wide-mouthed jar, and made into a paste with ether—specific gravity 0.75—after this the vessel is hermetically closed, and

the contents allowed to digest for twenty-four hours. At the expiration of this time the pasty contents are transferred to a strong linen bag and subjected to gradual pressure, when the ethereal extract of tannin, having a dark sirupy consistence, flows off into the receiver. This liquid must be evaporated to dryness at a gentle heat—100° to 110°—by which the tannic acid is left in the form of light-colored resin-like scales. The compressed residue is further treated with ether, to which six per cent. of water is added in the same manner as when preparing the first extract, and, on expelling the fluid by a gentle heat, a residue of tannin is obtained. It is, indeed, more impure than the product resulting from the method of PELOUZE, as it contains portions of chlorophyll, volatile oil, and gallic acid; still the tannin thus prepared answers very well for medicinal and other uses, for which it is applied in the arts.

Properties of Tannic Acid.—In its purity, tannic acid is colorless, inodorous, possesses a highly astringent taste, and is very soluble in water. It is, however, devoid of all bitterness, notwithstanding its astringency is so powerful. On testing the aqueous solution with litmus, the reaction evidences the acid nature of the tannin; and further, by treatment with an alkaline carbonate, carbonic acid is freely displaced, showing that a combination of the alkaline base and the tannin has taken place. With the oxides of the heavy metals it in a great measure combines, giving rise to precipitates which are the tannates of the respective bases, and generally possess a color more or less remarkable. Thus an infusion of nut-galls reacts in the following manner:—

With a *neutral* solution of salts of

	Precipitates given.	
	Brande.	Dumas.
Protoxide of manganese,.....	Dirty-yellow.	—
“ iron,.....	Purple-tint.	—
Sesquioxide of iron,.....	Black.	Blue-black.
Oxide of zinc,.....	Dirty-yellow.	—
“ tin,.....	Straw-yellow.	Yellowish.
Binoxide,.....	Fawn-yellow.	Yellowish.
Oxide of cadmium,.....	—	—
“ copper—protochloride,.....	Yellow-brown.	Grey.
“ —protonitrate,.....	Green.	Grey.
Oxide of lead,.....	Dingy-yellow.	White.

Teroxide of bismuth,.....	Yellow.	Orange.
Oxide of cobalt,.....	—	Yellowish-white.
Salts of cerium,.....	—	Yellowish.
“ titanium,.....	—	Blood-color.
“ tellurium,.....	—	Isabelle-yellow.
“ chromium,.....	—	Brown.
“ tantalum,.....	—	Orange.
“ molybdenum,.....	—	Brown.
“ uranium,.....	—	Brownish-red.
“ silver,.....	—	Pale-yellow.
“ platinum,.....	—	Greenish-shade.
“ gold,.....	—	Brown.
“ osmium,.....	—	Bluish-purple.

In making the foregoing experiments, it is necessary to employ neutral solutions of the salts, otherwise any excess of the acid may not only alter the shade of the precipitate, but prevent it altogether. This is especially the case with salts of iron and of titanium. When a solution of tannic acid is added to another of protosulphate of iron, according to DUMAS, no precipitate occurs; but if one of the sesquisulphate be substituted, there is an abundant deposit of a blue-black color.

By exposing an aqueous solution of tannic acid to the air, at a moderately elevated degree of heat, oxygen is freely absorbed, and an equal volume of carbonic acid is disengaged. Upon examination, the matter in solution will be found to be wholly transformed into two other substances, gallic and ellagic acids, the former of which is in excess, and is dissolved in the liquid, whilst the latter remains insoluble in the form of a yellowish powder.

This transformation takes place in the aqueous extract of gall-nuts much more readily than in one of pure tannin; this is particularly the case if the marcs or insoluble residue of the galls be left in contact with the liquid, as it induces a fermentative action, which brings about the transformation the more readily. When boiled with sulphuric or hydrochloric acid, gallic acid is also formed, together with grape sugar, which, as STRECKER states, remains in the mother liquid after the newly-formed acid is removed by crystallization. The change here induced may be represented thus, according to MILLER :—

A concentrated solution of caustic potassa at the boiling point has also the effect of transforming tannic into gallic acid; and if air or oxygen be admitted, of converting the latter into an ulmin-like substance. Hydrochloric, nitric, phosphoric, and arsenic acids, occasion in strong solutions of tannic acid white precipitates, which are, as stated by BERZELIUS, compounds of the tannin with those acids respectively. All these precipitates are, however, readily decomposed, and their tannin changed into gallic acid, by seething them with dilute sulphuric acid or with an excess of alkali. If a cold aqueous solution of tannin be mixed with another of gelatin, isinglass, bone-size, or glue in excess, an opaque white precipitate is obtained of tanno-gelatin, that is soluble by the aid of heat in the supernatant fluid. When, however, the conditions are reversed, and an excess of tannin is taken, it happens that instead of dissolving, the precipitate agglutinates, and forms a membranous matter of a greyish hue, that possesses considerable elasticity, and thus approximates to caoutchouc. The solutions filtered from these bodies strongly tinge those of the sesquisalts of iron. It appears that tannin solutions react in a similar way with protein compounds in general.

It was thought for a long time that the insolubility of the tanno-gelatin offered a means for insuring the purity of tannic acid, and of detecting the absence or presence of gallic acid in the sources affording tannin; but this insolubility, excepting in water alone, does not answer the purpose. PELOUZE employed a piece of skin, cleaned in the ordinary way from hair and epidermis; this was immersed for some hours in the extract, and the whole agitated occasionally, and finally the liquid filtered. When pure tannic acid was operated upon, the whole combined with the integument, so that the fluid had no astringent taste, nor did it color a solution of a sesquisalt of iron; but if gallic acid had been mixed with it, the bluish-black tint would present itself in the latter case.

Freshly precipitated alumina, agitated with a solution of tannin, absorbs the latter rapidly, and forms with it an insoluble composition; gallic acid behaves in a similar manner. At the temperature of an oil bath, tannic acid is decomposed, water and carbonic acid being formed; but when the heat is increased, other

products are generated, and nothing remains but charcoal, which, if heated on platinum wire, burns, leaving no residue. Strong ether dissolves tannin, and forms a sirupy liquid, which does not combine with fresh ether. Alcohol behaves with tannin in the same way, the solvent power of the spirit decreasing in reference to it as it approaches purity or dehydration.

From the analysis of BERZELIUS, it appeared that tannin was composed centesimally as follows :—

	Berzelius.	Pelouze.
Carbon,	52.69	51.40
Hydrogen,	3.86	3.51
Oxygen,	43.45	45.09
	100.00	100.00

These numbers nearly correspond with the formulæ, $\text{C}_{18} \text{H}_8 \text{O}_{12} = \text{C}_{18} \text{H}_8 \text{O}_9, 3 \text{HO}$; but STRECKER in his later researches gives the equation for gallo-tannic acid thus, $\text{C}_{54} \text{H}_{82} \text{O}_{34}$, showing that it contains less oxygen and hydrogen than is indicated above.

Varieties of Tannin.—As already stated, recent investigations have a tendency to the conclusion that tannin from the various vegetal products manifests such difference in its reactions with several substances, as to justify the recognition of many varieties of this compound, though classed under the above generic name. The impurity of this body was long considered to affect its behavior with reagents so as to vary the reaction; but, latterly, STENHOUSE and others have arrived at other conclusions, and regard the tannins from the different sources, and which give unlike reactions with reagents, as distinct chemical bodies. Doubtless, the other extractive matters in the solutions of the tannin modify to a great extent the color of the precipitate or other characteristics, from those afforded by the pure tannin, but all the difference cannot be attributed to this cause. With gelatin many of the tannins give well-marked indications, which would go far to show the dissimilarity in the nature of the tannin; yet it is upon their behavior with a solution of sesquisalt of iron that the discrimination is based. To ascertain this point, STENHOUSE prepared a reagent which affords indications only with the variety of tannin contained in galls and with gallic acid, and which consists in the production of pyrogallie acid when the body to be tested is submitted to the destructive distillation. In this way he observed that many varieties, which comported themselves exactly similar with sulphate of iron and in their general reactions, are by no means identical. Taking the behavior with solutions of sesquisalts of iron as the criterion, the following varieties are detected :—

1. *Tannin which forms a bluish-black precipitate in solutions of a sesquisalt of iron:*—Tannin from nut-galls, oak, poplar, beech, hazel, chestnut, maple, cherry, apricot, plum, elder, and other barks; sumach and logwood; from the roots of *lithrum salicaria*, *iris pseudacorus*, *geum urbanum*; *polygonum bistortum*—bistort; *alchemilla vulgaris*—ladies' mantle; from the leaves of the *arbutus uva ursi*—bearberry; *amothera biennis*, *geranium pratense*; from the husks of the *caesalpinia coriaria*; from lentils, *et cetera*.

2. *Tannin which forms a green precipitate in solu-*

tions of sesquisalts of iron:—Tannin from catechu—juice of the *mimosa catechu*; gum-kino—juice of the *coccoloba wifera*; most of the cinchona barks; horse-chestnut bark; the roots of the *rumez aquaticus*—water-dock; *tormentilla erecta*—septfoil; *krameria triandria*—ratany; *polypodium flex mas*—male fern; tea and badian; a species of anise; the leaves of *salvia officinalis*—sage; and of *arnica montana*—leopard's bane, and in date-stones.—*Morfit*.

Artificial Tannin.—Besides the foregoing, chemists distinguish other varieties of tannin which result from the chemical action of several powerful agents upon many substances; as, for instance, from the action of nitric acid upon charcoal and indigo, and likewise from the effects of sulphuric acid upon resins and camphor. The first notice of artificial tannin was published by HATCHETT in the Transactions of the Royal Society in 1801: he discovered it whilst making experiments upon the slow carbonization of plants. This tannin is different, however, from other varieties of this substance at present known. When one part of charcoal, reduced to an impalpable powder, is digested with five parts of nitric acid of spec. grav. 1.40, and ten of water at a moderate heat, the fluid being added portionwise to the charcoal, the latter after a time disappears, and a transparent deep-brown liquor remains, which, on evaporation, leaves the artificial tannin slightly impregnated with acid. By repeated solutions in water, and evaporations, this impurity may be removed. From the above materials about 1.2 of artificial tannin is obtained.

Artificial tannin prepared in this way is a brown, inodorous substance, having a vitreous fracture, and very soluble in water. THOMSON states that alcohol of spec. grav. 0.80 dissolves it, and so far it manifests a difference of behavior from natural tannin. The aqueous solution of this substance precipitates gelatin of a brown color, but the shade deepens as the liquids are more dense. This precipitate is a compound of tannin and gelatin, in the proportion of thirty-six parts of the former to sixty-four of the latter. It is insoluble both in hot and cold water. With the alkaline bases it combines, forming more highly-colored solutions, which, in the course of some time, get cloudy. The ammoniacal solution of artificial tannin, on being evaporated to dryness and redissolved, will not precipitate with gelatin till after the alkali which it retained is neutralized with an acid. The alkaline earths precipitate it, but the precipitates are slightly soluble in water; the heavy oxides throw it down in combination as a puce-colored substance. On treating the precipitate with nitric acid, the artificial tannin dissolves without change, whereas the natural product is altered by this agent. Heated alone in a retort, it yields water and nitric acid, ammonia, carbonic acid, and another gaseous substance, probably nitrogen. According to CHEVREUL, this variety of tannin is a compound of nitrous or nitric acid with a carbonaceous matter.

A second kind of tannin is produced when indigo, or similar compounds rich in carbon, are treated with nitric acid, as in the foregoing method. A very bitter, orange-colored residue is obtained, which is soluble in water,

precipitates gelatin and metallic bases, and affords, when decomposed, nitrous or nitric acid. If sulphuric acid be made to react upon resin or camphor till these dissolve, and heat be applied till the liquor blackens, and then cold water added, a black powder falls which, when treated with alcohol and the spiritous extract evaporated, yields a residue which is a third kind of tannin compound. This variety precipitates gelatin and some of the bases. CHEVREUL considers that this compound contains sulphide of hydrogen.

Uses of Tannin.—The range of the application of tannic acid is not very extensive. It will be already understood to be of primary importance in the manufacture of leather; but, besides this application, it serves another purpose in wine-growing countries, namely, of precipitating the *glaiadine* from the fermented *must*, especially of white wines. The removal of this principle is of very great importance to the vintner, for if it be suffered to remain, it is apt to induce a secondary viscous fermentation, which would destroy the wine. Tannic acid seems to be the best antidote in this instance, since it coagulates the *glaiadine*, and forms a tannate with it. Tannic acid is also extensively employed as a medicine on account of its powerful astringent properties, which are readily explained by what has been said regarding its action on albumen, fibrin, and gelatin. Its effects are to check hæmorrhages, profuse secretions, and to constrict relaxed fibres; and for either purpose it may be administered either internally or externally. When taken into the system, it would appear that it is capable of being converted into gallic acid, pyrogallie acid, and a humus-like substance, all of which may be detected in the urine; but this change does not seem to have been effected till the tannin has exhibited its peculiar astringent action. In the laboratory, tannic acid is occasionally employed as a test.

GALLIC ACID.—The tendency of tannic to be transformed into gallic acid has been already mentioned; but it may be well to show more in detail the circumstances under which this change is effected, and to point out the properties of gallic acid generally, as also with regard to the operations of the tanner. Its name has been derived, as is evident, from galls, on account of those excrescences containing it ready-formed; it likewise exists in the cypress-nut, *arnica* flowers, white hellebore, meadow saffron—*colchicum autumnale*—and in a number of astringent barks, together with tannic acid, but in small quantities. Its most prolific source is tannic acid, which, by oxidation, yields it abundantly. The conditions affecting the change, such as exposure of the solution of tannin to air and at an increased temperature, have been already mentioned, as likewise the decomposition of the same body by the mineral acids. All the methods recommended for the production of gallic acid from tannin, are based upon these properties of the latter. Thus BRACONNOT prepares it from powdered nut-galls, by drenching this substance with water and maintaining a temperature of 70° to 75°. After a while a quiet action succeeds, and when this subsides the pasty mass is to be expressed and afterwards heated with boiling water, which dissolves out the gallic acid, and yields it upon

evaporation in impure crystals. These, by re-solution in water and filtration of the liquid through animal charcoal, afford a menstruum which gives the gallic acid in a state of purity when concentrated. WITHELL prepares it by treating thirteen drachms of dry tannin with two fluid ounces of sulphuric acid of 1.84°, diluted with four times its volume of water and the application of a boiling heat. Gallic acid in crystals is deposited to the amount of eighty per cent. of the tannin employed.

It would appear from various researches, that the change of tannin to gallic acid, on exposing the extract containing the former to air and moisture, is due to a fermentative process, which is considerably expedited if the vegetal matter in the bark or gall, or whatever else the source may be, is permitted to remain in contact with the liquid. Such is the case, especially, with extract of gall-nuts; and it might be inferred that the tannin from all other sources, and which is capable of being transformed into gallic acid by oxidation in the above manner, is similarly affected. M. LAROCHE, has shown by comparative experiments the effect of the marcs of gall-nuts, after the extraction of the tannin with ether in the ordinary way, in operating this change. By inclosing an aqueous solution of tannin and a portion of this residue in a bottle or flask, and allowing it to remain for some time, he found that the tannin was entirely converted into gallic acid, whilst a strong extract of tannin, freely exposed to the air at the same time, retained nearly the whole of its tannin unaltered. Hence, doubtless, the insoluble matter in galls in the presence of moisture, is capable of acting on tannin as a ferment, and that the change of tannin into its derivative is the result of a fermentation. It is well known that fermentation by contact of yeast, blood, and albumen, effects the same transformation of the astringent extract as the residue of the galls which have been digested in ether, and also that the latter will excite the vinous fermentation in solutions of grape-sugar, and, therefore, these reactions may be taken as mutually corroborative. Further, the gallic fermentation may be intercepted by antiseptics, like the vinous. Protochloride of mercury—corrosive sublimate—completely prevents the decomposition; and pyroligneous acid, or carbonic acid, as shown by the investigation of CALVERT, on account of some empyreumatic matter which it contains, likewise considerably retards the fermentation.

It has been shown, that sulphuric and hydrochloric acids at a boiling heat rapidly change tannin into gallic acid, and without the intervention of air; but if the mixture be kept at a common temperature, M. ANTOINE has shown by his researches that the decomposition of the tannin is retarded by a small portion of those acids. On the contrary, tartaric, malic, and vegetal acids in general, expedite the decomposition of the tannin. The rapidity with which sumac ferments, may be referred to the quantity of malic acid in the leaves.—Parnell.

Properties of Gallic Acid.—When pure, this acid crystallizes in long silky needles, which are unalterable in the air; its taste is acrid and styptic. BRACONNOT states that it dissolves in a hundred parts of cold, and in about three parts of hot water; four or five

parts of alcohol in the cold dissolve it, but one part of the hot spirit will take it up. It is soluble in ether, but in less quantity. The aqueous and spirituous solutions, but the former more readily, undergo decomposition, so that the surface of the liquid becomes mouldy, and a brownish matter is produced, which DÖBEREINER considered ulmin. Added to a solution of gelatin, no precipitation occurs—a behavior which at once distinguishes gallic from tannic acid, and which indicates that it is unavailable in converting skin into leather. This being so, and, as has been already pointed out, tannin being readily convertible into this body, it becomes of the utmost importance to the tanner to guard against this transformation, which, in the usual way of tanning, is so apt to take place. The researches of LAROCQUE have shown that, in regard of the tannin from galls, the decomposition is completely and readily effected, provided the insoluble residuary matter be allowed to remain in contact with the liquor containing the tannic acid, and it is equally well known that the tannin from sumac is liable to decomposition, as well when it remains in contact with the insoluble portion of this body, as when it is separated from it; but independently of the action of the residue, the malic acid here plays an important part. Though the evidence proving that the insoluble portion of the barks, *et cetera*, employed in tanning, when allowed to remain in the tan-liquor, does operate in the rapid conversion of tannin into gallic acid, thereby rendering the former valuable body useless, is not definite,—still, knowing that in the waste tan-liquor, a large quantity of gallic acid is found, it may be safely stated that its production is from the tanning, and also is owing more to the effects of the insoluble matter of the source of the tannin, than to any oxidation which might take place during the tanning processes. Even those kinds of tannin which are incapable of producing gallic acid by decomposition are subject to a metamorphosis which destroys the tanning agent, and this fermenting action is more readily produced when the insoluble matter is left in contact, than if the liquor were retained by itself. The only benefit which the tanner derives from gallic acid is, that it aids in swelling the hides, and thus facilitates the absorption of the tannin; but when it is considered that a dilute solution of sulphuric or vegetal acids effect the same thing quite as well, it will be evident that he who relies on the swelling by gallic acid, and sacrifices a corresponding portion of tannin in its production, suffers a considerable loss, and is not fit to compete with those who can obviate such a sacrifice.

At 410° to 420°, according to the observation of PELOUZE, gallic acid is entirely volatilized, producing a sublimate of beautiful white crystals and pure carbonic acid; if the heat be urged to 464° or 482°, instead of the foregoing change, another takes place, in which pure carbonic acid is likewise developed. But in addition to this a quantity of water is produced, and which runs along the sides of the retort, in the bottom of which remains a considerable mass of brilliant-black insoluble matter, which at first sight might be taken for charcoal. It is, however, a true acid, and is called by PELOUZE, meta-gallic acid.

According to the above-named chemist, crystallized gallic acid is composed of—

	Centesimally.
Carbon,	50.10
Hydrogen,	3.64
Oxygen,	46.26
	100.00

numbers which agree with the formula, $C_7 H_3 O_5$, HO; STRECKER, however, regards it as a tribasic acid, thus $C_{14} H_6 O_{10}$, $2HO=3 HO$, $C_{14} H_3 O_7$, 2 aq.—and capable of forming salts which correspond with the general formula, MO , $2 HO$, $C_{14} H_3 O_7$; 2 MO , HO , $C_{14} H_3 O_7$, and 3 MO , $C_{14} H_3 O_7$; MO being here the representative of a metallic oxide.

As pyrogallic acid, $C_7 H_3 O_5$ or $C_{14} H_6 O_{10}$, meta-gallic acid, $C_7 H_2 O_5$ or $C_{14} H_4 O_{10}$, ellagic acid, $C_{14} H_2 O_7$, HO , and other derivatives from gallic acid and, therefore, remotely from tannic acid, are of no importance in the making of leather, they will not be further dwelt upon. Ellagic acid is said, however, to be the chief agent that gives the bloom to the tanned hide.

SUBSTANCES USED IN TANNING.—Those which are available for the purposes of tanning, embrace a wide range if the juices, barks, leaves, roots, fruit, and

excrescences of trees, and also vegetals which contain tannin of one kind or other, be taken into account. In looking over the researches and labors of chemists, many hundred substances which yield tannin have been discovered; but practice, or the trade, recognizes only a few of these, probably owing to the quantity which can be annually produced, their yield of tannin, or because they offer some advantage either in making a better leather, or in the time required to effect the operation. The tannin and other distinct principles in vegetal growth of every kind, are derived from the sap or soluble matters, imbibed by the rootlets from the soil in which the plant exists, and the gases absorbed by the foliage. In many plants which elaborate tannin, it is met with in small proportions, owing perhaps to its being only a secondary, and not a primary secretion. It is found in some vegetals equally in all parts, whilst in others certain parts are richer in this substance, the remaining exhibiting only slight indications of its presence. The particular portions of plants that yield the greatest amount of tannin are, therefore, preferred in making leather.

The following is a list of the materials which contain tannin in the largest quantities, and which may be employed in the manufacture of leather.

INSPISSATED AND PREPARED EXTRACTS,	{ Kino, Catechu, <i>Terra japonica</i> , or Cutch.
VEGETAL EXCRESCENCES,	Galls.
	Of the different kinds of willow.
	Of the <i>quercus robur</i> —common oak; <i>quercus cerris</i> —Turkey oak; <i>quercus ilex</i> —evergreen oak—and other varieties.
	Of the <i>erica vulgaris</i> , or common heath, and of other varieties of the same plant.
TREE LEAVES,	Of the <i>cyndra scolymus</i> —garden artichoke.
	Of the sloe-tree— <i>prunus spinosa</i> .
	Of the <i>conium maculata</i> —spotted hemlock.
	Of the <i>arbutus uva ursi</i> —bear-berry.
	Of the <i>thea Chinensis</i> —the leaves of the several varieties of green and black teas yield tannin—and of the <i>rhus glabrum</i> , known as <i>sumac</i> .
FLOWERS AND TREE TOPS, FRUITS,	These are hardly ever employed, although many afford extracts which precipitate gelatin and salts of iron.
	Of the grape.
	Of the <i>hydro-sapathum</i> and wild cornel.
SEEDS AND BULBS,	The hulls of the fruit of the <i>casalpina coriaria</i> , known under the title of divi-divi, or leby-diby.
	The bulbs of the <i>scuilla maritima</i> .
	The dried acorn hulls of the prickly-cupped oak— <i>quercus agrifolia</i> .
WOODS,	All woods or trees, the barks of which yield tannin, also afford more or less of this substance; they are, however, scarcely ever employed.
	Of the dentillaria, or lead-wort— <i>plumbago Europaea</i> .
	Of the male fern— <i>aspidium filix mas</i> .
ROOTS,	Ratany— <i>krameria triandria</i> —root.
	Of leopard's bane— <i>arnica montana</i> .
	Of statice, or marsh rosemary.
	Common bark, of which there are several varieties; birch, chestnut, and horse-chestnut barks; sassafras, or the bark of the root of the <i>laurus sassafras</i> ; larch, hazel, beech, Lombardy poplar, blackthorn, pomegranate, ash, elm, cork-tree, cinchona, willow, sycamore, tulip-tree, wattle and oak barks; besides these, however, there are other barks—such as that of the sumac shrub, winter's bark, <i>et cetera</i> —that afford tannin in available quantities.
BARKS,	

It will not be uninteresting to state briefly some of the properties of the substances mentioned in the foregoing table, with respect to their uses for tanning purposes.

KINO.—Of the inspissated extracts which are found in the market, kino or gum-kino, is the richest in tannin, containing, as it does, according to VAUQUELIN'S analysis, seventy-five per cent. of this compound. Nevertheless, it has not hitherto come into use for tanning purposes, but is solely devoted to medical uses. For its more general properties, refer to page 316, Vol. II.

CATECHU.—Catechu is another of the same class as the preceding, and forms a most useful article for the tanner. There are several varieties which are distinguished by various names, such as cutch, terra japonica, and gambir. Formerly, this extract, from its brownish-red color, was supposed to be a kind of earth, hence the title *terra* given to it. Catechu is extracted from the acacia catechu, a tree which grows to the height of twenty or thirty feet, and abounds in the forests from latitude 26° to 30° , known as the Bornese territory on the Malabar coast, and called Cancan. The heart and bark of the wood are boiled in water, and the solution

evaporated, which leaves the astringent extract known as Cancan catechu. According to NEES VON ESENBECK, most of the catechu exported from Bombay is prepared from the acacia catechu, whilst that brought from Bengal, is derived from the *uncaria gambir*, a shrub cultivated in the countries lying on both sides of the shores of Malacca. It is obtained by boiling the wood, bark, and leaves of this shrub together with the inspissated juice in water, and evaporating, then adding a little sago to give it consistency; it is finally exsiccated in the sun, and then cut into square or circular cakes to suit the purchaser. Bombay catechu, which is the richest in tannin, is of a dark brownish-red hue, both externally and internally, and possesses a specific gravity of 1.38. DAVY examined the Cancan catechu, and found it to be 1.39; he also found in two hundred parts of this, as well as of the Bengal catechu, and known by the title *Pegu*, from the province of Bengal where it is prepared, the following constituents:—

	Cancan or Bombay catechu.	Pegu or Bengal catechu.
Tannin,.....	109	97
Extractive,.....	68	73
Mucilage,.....	13	16
Earthy residue,.....	10	14
	200	200

The genuine catechu, of whatever variety, contains, on an average, about half its weight of tannin, and its efficacy in making skin into leather, has been estimated as being five times greater than the best oak bark; but this seems exaggerated. Besides the real tannin, the extractive matter contained in it is another definite substance, which is called *catechin* or *catechuic acid*, and which, doubtless, plays a part in the process of tanning. To it is ascribed the property of coloring the leather so deeply. The latter body differs from the tannin in being insoluble in cold water, although a solution of the tannin of catechu takes up a small quantity of it. The varieties of catechu of commerce are:—

1. *Cake catechu*, from its being in circular cakes. Their color varies from a light-brown to a black, and their weight from several ounces to two pounds.

2. *Pegu catechu*.—As already stated, this variety obtains its name from the province where it is prepared. It is generally imported in masses of a hundred pounds weight, but as seen in the shops, it presents the appearance of angular irregular fragments in double layers, with leaves between. It has a compact shining fracture, and a deep-brown color.

3. *Bengal catechu* is manufactured in rectangular cakes, but in the course of transit they get reduced to fragments. Externally, it has a rusty brown color, and internally, the shade varies from a brownish-grey to dark-brown.

4. *Bombay catechu*.—This variety occurs in globular lumps of the size of an orange flattened, and two pieces generally adhering together. In color it resembles that brought from Bengal.

5. *Gambir*.—It is stated by M'CULLOCH that no less than four thousand six hundred tons of catechu, under the name of *gambir*, is produced annually by the Chinese settlers in Rhio. It takes its name from the shrub which is its source, the *uncaria* or *nuclea*

gambir. It has a deep yellow or reddish-brown color on the outside, but within it is paler, and presents a dull earthy fracture. It comes to these countries in solids of about a cubic inch. ESENBECK, who examined this variety, states that it yields from thirty-six to forty per cent. of tannin. Boiling water entirely dissolves it.

6. *Arecha catechu*.—The nuts of an Indian palm known by this title, afford this kind of astringent substance. These fruits are macerated with water, and the decoction evaporated, when a better sort of catechu results, known by the term *kassu*, and the semi-exhausted residue upon further treating it with water, affords a solid extract, which is distinguished as *coury*. The former is of a black color, and intermixed with husks, and the latter of a yellowish-brown, with an earthy fracture. The *coury* is, of course, inferior to extract known as *kassu*.

With regard to the application of catechu to the manufacture of leather, the natives of India have long practised it; but its introduction into the trade of this country for a similar purpose, is of modern date. Its richness in the tanning agent causes it to be very rapid in producing a gelatino-tannate of the substance of the skin, or, in other words, of making leather. The qualities of the article manufactured from it, are not, however, so satisfactory as the rapidity of its effects, either to the tanner or the public: for the leather is very permeable to water, light and spongy, hard, and of a dark-reddish fawn color. The characteristic deposit from oak bark and a few other tanning agents, known as *bloom*, is not produced by catechu, and this want is a material objection to its use, as the existence of *bloom* upon leather is considered as a kind of guarantee of its goodness. One pound of catechu, of first-rate quality, is capable of producing one pound of leather, and, consequently, in tanning power is equivalent to five of oak bark, or thereabouts, as already stated.

Besides the inspissated juices just mentioned, there is another which, though not yet introduced into the European trade, has, nevertheless, been employed by the North-western Indians for tanning purposes. This is gum-butea, the account of which will be found at page 315, Vol. II.

GALLS.—There is no other natural product that affords so much tannin as those round, hard, woody excrescences known as galls. Formerly it was supposed that these were a kind of fruit; but naturalists and physiologists have ascertained that this is not the case, but that they are excrescences or tumors which form on the branches of different trees and vegetables, owing to the puncture of certain insects, for the purpose of depositing their eggs. The tree which affords those galls that are commonly known as *nut-galls*, is a stunted species of oak—*quercus infectoria*—which is very general throughout Asia Minor. It grows to the height of four or six feet, has a crooked stem, and yields an acorn two or three times larger than its cup. The gall-flies, which occasion the gall, belong to the genus *cynips*, and, from different accounts, there are several species; that which is concerned in producing the officinal galls, is the *cynips gallæ tinctoriæ*. The female insect of this variety, by means of an appropriate apparatus, per-

forates the cortical part of the plant, and in the wound deposits her eggs, together with an acrid liquor. In two or three days the part is, as it were, inflamed, and a swelling appears, and continues to increase till it results in a gall. The eggs which are inclosed in this excrescence are hatched, and in due time the young larvæ appear, and develop themselves, being supported by the juices of the plant till they become a perfect insect, when they perforate the gall and escape. When this happens, the excrescence loses much of its astringent principle, and becomes lighter; but if gathered or harvested before the entombed insect is completely developed, the nuts are not only heavier, but are richer in tannin, and command a better price in the market. Galls gathered before the escape of the insect, have a black or bluish shade, but when the insect has left, their color is paler, and they generally attain to a larger size. To prevent this occurrence, great care is taken to harvest the galls before the insect attains its full growth, and eats its way through, leaving them, however, on the trees till they have acquired their greatest weight. In some parts the governor, or *aga* of the district, levies a tax on the produce; and being thus interested in the success of the crop, he causes the cultivators to traverse frequently the hills and mountains

to report upon the advanced state of the galls, and wherever the proper growth has been attained, they are immediately collected. The selections thus made are known in the market as *green-galls*, and come to these countries from Aleppo, Smyrna, and the interior of Asia Minor. Those which escape harvesting before the entombed insect has attained its full growth or emerged, are known as *white-galls*, and are imported from the same place. Another kind of gall, produced upon the oaks growing in many departments in France, are nearly equal in size to the Asiatic green-galls, but they are rounder, and possess a smooth and in some instances a polished surface. They have a brownish color, and rank in their content of tannin intermediate between the green and white Aleppo galls. A variety originating from the puncture of an insect allied to the *aphis* on the branches and shoots of the *distylium racemosum* comes from Japan. They are of an irregular shape, having in some instances both ends small, whilst the middle is much thicker, but more generally the stem end is the least and the more swollen part is near the other. Hence they are called commercially apple-galls.

Annexed are the analyses of samples of Aleppo and Chinese galls by two distinguished authorities:—

LEAVES.—Of the foliage of trees containing tannin, very few, if any, are now employed in the manufacture of leather. The leaves of the heath were once extensively used in this country; but this material has long been abandoned, preference being given to oak barks and other substances of native and foreign growth.

The leaves of the sloe-tree—*prunus spinosa*—were likewise used to some extent in London for tanning calf skins, by employing a decoction prepared by boiling the leaves in barley water. So also it is stated in the *Bibliothèque Physico Economique* for 1789, that garden artichoke was resorted to for preparing calf and goatskins for bookbinders' use, and that the operation was as successful as if nut-galls or willow bark had been the tanning agent.

The various species of tea yield variable but large quantities of tannin, amounting from thirteen per cent., according to MULDER—to thirty-five and even forty per cent., according to FRANCK. The value of this article, however, as a luxury and dietary, precludes its employment in the production of leather.

Sumac.—In its purity it consists of the powdered leaves of a shrub that grows extensively in the south of Europe, in the United States, and in Asia to which it is indigenous. It seems that there are several species

such as the *rhus cotinus*—wild olive—*rhus glabrum* or *coriaria*, which is the best and most esteemed for the preparation of the finer kinds of leather. Italy, Sicily, Portugal, Spain, and France produce considerable quantities of sumac, varying in quality, and distinguished from one another by the habits of the tree, the color, and other properties. The sumac obtained from the *rhus cotinus* is for the most part employed in dyeing, and the product of the *rhus coriaria* is that which is converted to the uses of the tanner, especially in the preparation of morocco and similar leather. The latter shrub which grows wild in Portugal, Spain, and other countries named above, rises to the height of four to eight, and in some cases to twelve feet; its stem is crooked and covered with a reddish-grey bark; the leaves present a green on the upper and a whitish color on the under surface during spring and summer, but they assume a reddish hue in autumn. It flowers in July, the blossom being greenish-red, and yields a cluster of small crimson berries on ripening. Regarding the effect of sumac as a tanning agent, it is stated that it deprives the skin of much of its softness and elasticity, but it offers one great advantage of not coloring it during the process, and is on this account preferred in France and other places, notwithstanding its cost being

much greater than other tanning agents, by the fabricators of morocco and glazed leather. It is utilized in the ordinary way of tanning mixed with bark or other matter, and affords good results.

Of the species of sumac in the market, the Sicilian is accounted the best. There are two kinds, one of which, the Alcamo, is the most esteemed. It is a very fine light-green powder, containing very little woody matter, having an agreeable odor analogous to that of the violet, and a strong astringent taste; it contains very little coloring matter, though it gives a yellowish green solution when macerated with water. The second variety inclines to a reddish yellow, has a feebler odor, with a less astringent taste than the foregoing variety. On this account it is not much employed in tanning, though extensively used in dyeing; see vol. i. pp. 579, 629. Sicilian sumac is generally packed in bales weighing about one hundred and a half.

Spanish sumac is various in quality, being less carefully prepared, and, consequently, more or less mixed with woody matter. The best sort comes from Priego, and is grown in the neighborhood of Malaga. It is, like the Sicilian, finely ground, and affords a color of equal or greater brightness; its odor reminds one of the tea plant. With water it gives a dark and more reddish solution than the foregoing. It is usually packed in bales of one hundredweight. The other sorts, the Molina and Valladolid sumac, are next in quality to the foregoing; they are very similar.

Portuguese or Porto sumac is almost similar to the Priego, but is generally dirtier, and contains more mineral salts.

Italian sumac has a dark-green color, is free from woody matter, but feels granular in the hand, and has an odor like that of the bark, which possesses similar qualities as the leaves.

French sumac is similar to the preceding. Three sorts are collected, the Fauvis is almost equal to the Sicilian when well purified, and comes from Brignolles, near Marseilles. If less care be taken in its manufacture, it approaches more to the quality of Malaga sumac. It frequently goes under both these names. A second sort, Donzere, and a third, Pudis, are commonly used in the tanneries. A fourth variety, called *redou* or *redoul*, obtained from the *coriaria myrtifolia*, cultivated in Languedoc, is of a greyish-green color.

The operations involved in the preparation of sumac, consist in collecting the branches of the shrub whilst in full foliage, drying them in the sun, and then separating the leaves by threshing, or other means. Subsequently the detached leaves are ground under vertical mill-stones, and packed in bales for the market. In some cases, the peduncles and more tender branches are ground with the leaves; but as these contain a good deal of tanning material, they do not so much injure the quality.

FLOWERS AND FRUITS—Valonia.—Hitherto flowers and flower-tops, though containing tannin, have not been used in the preparation of leather on the large scale. The same might be said of fruits, with the exception of the acorn-cups of the *quercus agilops*—prickly-cupped oak,—a tree which grows in abun-

dance in the Morea and the adjacent countries. In commerce, they pass under the title *valonia*, and are imported from Turkey, Greece, Italy, and India. When the fruit is gathered, it is conveyed to the nearest port to be shipped; there it is stored in a warehouse during several months, being laid out in beds of three to five feet in thickness. A slight heating or fermentation sets in during the above period, and as the moisture escapes, the long spreading scales, which hitherto confined the acorn become contracted, and allow the latter to fall out of the cup. After being well dried the whole is picked, and the acorns which contain no tannin and the damaged cups are separated from those of the latter that are dry and good. The cup of this acorn, so long as kept dry, retains a bright drab color; but when exposed to moisture, it loses this appearance and turns black, losing by the change its tanning properties. Doubtless, to the long exposure of the upper cups to the disengaged vapor from the bed, is owing their being invariably more or less damaged. Ordinary or common *valonia*, the cups of which average about two inches diameter, differs from that kind known as *camata*, or *comatena valonia*, which are only about the size of a large cherry. The latter is said to be the fruit of a smaller species of *quercus* than that which affords the common *valonia*. It is in greater demand for silk-dyeing than for tanning.

Leather prepared with *valonia* is said to be harder and less permeable to water than that made with oak-bark; and, besides, it presents the advantage of readily depositing a rich bloom upon the leather, a characteristic much sought by the traders in this article. Not less than from ten to twelve thousand tons of this tanning agent are annually imported into Great Britain and Ireland, and it is stated that two pounds of good average quality are sufficient for making one pound of leather. The duty, which up to 1842 was twenty shillings per ton, was then reduced to five shillings, and entirely removed in 1845. Its price varies from ten to twenty pounds per ton, according to the stock and seasons.

Myrobalans, the dried fruit of various species of *terminalia*, is extensively employed in tanning and dyeing factories. There are several kinds, all of which come, however, from the East Indies, by Calcutta and other ports. This sort of fruit when ripe is pear-shaped, deeply wrinkled, of brownish-yellow hue, and weighing from seventy to one hundred grains. The whole of the astringent matter which it yields is contained in the husk, which is easily separated from the inclosed nut by bruising the whole; besides the tannin, a yellow coloring matter with mucilage and other principles is extracted. The tannin from this source differs but slightly, according to STENHOUSE, from that found in nut-galls.

Divi-divi is an article which has acquired, within a comparatively modern date, an interest with tanners and commercial men. It may be classed with the foregoing, since it consists of the dried pods of a leguminous shrub—*caesalpina coriaria*—which is indigenous to South America, and grows to the height of twenty and even thirty feet. The pods are about three inches

long, of a dark brown color, and curled up as if they had been submitted to a high temperature during desiccation. The whole of the tannin is concentrated in the rind of the pod, immediately beneath the epidermis, and has consequently a very astringent taste, but the inner portion that incloses the seed is very insipid. Besides tannin, it yields coloring matter, and a mucilaginous substance which interferes with its application in dyeing and printing. The leather prepared with divi-divi is very porous, and tinged brown or brownish-red, according to the density of the ooze, time allowed, and state of exposure to the air. Its formation is attributed to a fermentative change induced by some of the extracted matters; this change occurs as well in cold as in warm weather, but more frequently in the latter. During the reaction, a reddish matter deposits upon the leather in course of preparation, and on the sides of the pit. By preventing oxidation of some of the principles present, through the exclusion of atmospheric air, none of the forementioned substance appears, and the leather retains the natural color. A solution, or extract of divi-divi, readily affords a deposit of bloom to leather. STENHOUSE has shown that the tanning matter of divi-divi, though similar to that contained in galls, inasmuch as it exerts a like reaction on solutions of sesquisalts of iron, is, nevertheless, different from the latter, since it produces no pyrogallie acid when submitted to dry distillation.

WOOD.—This material has not been converted to any useful end so far as it immediately concerns tanning, notwithstanding, that tannin, as before stated, exists to some extent in many species.

ROOTS.—Several substances of this nature may be advantageously applied in tanning. The root of the common avens, *geum urbanum*, contains, as shown by TROMSDORFF's analysis, forty-one per cent of tannin. This plant is perennial, and is indigenous to Europe; it grows wild generally in damp and shady places. The root is about a quarter of an inch in thickness, has long descending fibres, and appears in alternated layers of red and white, the former predominating. It should be gathered in spring, and dried cautiously at an incipient heat. It has a slightly bitter and astringent taste, and, in the dry state, an odor not unlike cloves.

Ratany root is another substance very rich in tannin. MORFIT describes this shrub—*krameria triandria*—as being indigenous to Peru, growing in mountainous districts, and flowering at all seasons. As found in commerce, it is in pieces of irregular shape and size, some not thicker than a pipe-stem, and others an inch in diameter, and two or three feet long. Occasionally, several of the stems issue from one head. The bark is of a dark yellow or brown color, readily separable from the wood, and has an astringent, nauseous, and slightly bitter taste. The woody part has less taste, and a color approaching to red. Water at 212° dissolves the valuable principles, and the decoction, which has a deep-brown color, is abundantly precipitated by the mineral acids. The alkalies only change its color to that of urine. Sulphate of iron produces a black, and acids a fawn-colored precipitate. Gelatin proves the presence of tannin. The following

analyses by GMELIN and PESCHIER indicate the composition centesimally:—

TOURNAL has drawn attention to a perennial plant growing wild in the south of France, the dentillaria or leadwort—*plumbago Europæa*—on account of its contents of tannin. The same chemist has made reference to the *statice* or marsh rosemary, and suggested its being employed as a substitute for oak bark. The Kalmucs, it is stated, use a decoction of this plant and sour milk, for tanning the skins of sheep and goats so as to be available for clothing.

BARKS.—This species of tanning material is by far more generally preferred in tanneries than any other, and that which ranks of highest importance for the purpose is oak bark. There are several kinds of this substance, varying more or less in their amount of tannic acid; these, however, come under two classes—the evergreen and deciduous oak barks. Like most of those substances already described, the virtues of the oak and other barks are not disseminated equally in the several parts; indeed, in the rind of the common oak of these countries, there are portions in which no tanning or other valuable secretion is found. In examining the exterior covering of trees generally, a very great analogy will be observed between it and the skin of animals. For instance, the *epidermis* or outer thin, dry, and occasionally transparent layer of matter, has its analogue in that of the skin; and, like the latter, it is thrown off as the tree grows old and increases in size, owing to the formation of internal layers of other matter, which cause the epidermis to fracture and ultimately to fall off. The matter beneath the epidermis is a layer of cellular substance, which partakes more or less of the vitality of the tree. It is generally the seat of the green color, and, like the *rete mucosum* of animals, is being constantly dried up into the epidermis exteriorly, whilst the secretion of herbaceous matter from the interior maintains it in the normal state. Beneath this is found the *cortical* tissue, of which, as the tree grows older, the woody matter is formed. In it are found all the valuable secretions of the tree, such as gum, sugar, resin, oil, and the other matters which are so generally applied in medicine and the arts. It is constituted of a number of elongated cells, divided into layers by a variety of longitudinal woody fibres. This is more particularly the case with the inner portion of this layer, and which is called the *liber* from its organized appearance. It immediately overlays the real ligneous matter, or wood of the tree. In its general construction it resembles in a measure the last-mentioned, only that there are more longitudinal

fibres, forming as it were leaves or laminæ, being reticulated and bound together by cellular substance. These layers may be separated by macerating the *liber* in water, which removes the cellulose, so that they appear like the pages of a book, and hence the term *liber* applied to it. It is this portion that is annually converted into wood, and which gives to the transverse section of the heart of the tree the annular appearance it presents, and which is generally termed the *grain*. Each of these rings represents a year's growth of woody fibre.

As regards tannin, the parts of the *cortex*, or true bark, in which it is mostly contained, are the exterior layers of the portion known as the *liber*, and the interior of the cortical tissue—the inside portions of the former, and the most exterior of the latter, yielding very little of this principle. The same observation is true of other matters, such as quinine and the like. The various dyes are seated frequently in the exterior portion of the cortical tissue. The sap always ascends through the cellulose of the real bark; and as this fluid is the source from which tannin is secreted, it is evident that there will be more of it in the bark, when the flow is greater than at other periods. Experiments have proved this to be the case as regards oak, and the same observation applies to the barks of other trees, such as the willow, elm, pine, birch, beech, *et cetera*, with equal force.

It may be well to state here, as briefly as possible, the nature and peculiarities of the more important barks referred to at page 500, with the view of showing their adaptability for tanning. In this digest, considerable information has been obtained from Professor MORFIT'S very copious work on tanning and currying leather. The bark of the cinnamon-tree, though yielding tannin, has not yet been employed for the manufacture of leather. Larch and birch barks are resorted to in a very limited way, being in Great Britain and Ireland applied only for tanning bazils and other sheep-skin leather. In the larch-tree bark the tannin amounts to two per cent.; but in that of birch, DAVY found 6.75-parts centesimally. Birch bark is very much employed in Russia for making the fancy red-colored leather, known in that country as *jucten*, and other kinds, and the peculiar resisting powers, as well as its odor, are attributed to the assimilation of the oil which this bark contains. The American variety of the chestnut-tree bark yields four per cent. of tanning material, and the leather prepared from it is said to be more flexible than that made with oak bark. The bark of the Spanish chestnut contains, according to DAVY, four per cent. of tannin. In the United States, the bark of the hemlock spruce, a species of fir—*abies canadensis*—is much used for tanning as a substitute for oak bark. MORFIT states that this tree, which grows to the height of seventy to eighty feet, constitutes three-fourths of the evergreen woods in Nova Scotia, New Brunswick, Maine, Vermont, and part of New Hampshire; it is less common further South, though found in the middle and Southern states on the Alleghanies. The bark of this tree is grey when young, but grows lighter when old, and is generally covered with moss. In June the barking is effected, and before

being ground half of the epidermis is shaved off. Leather made with this bark is reddish, and is judged inferior to that yielded by oak bark; however, the two barks worked together are supposed to afford a better product than oak tan produces by itself. DAVY found in the bark of the beech about three per cent. of tannin. Some varieties are employed by the tanner when oak bark happens to be scarce, but the leather from it is white and inferior. The same chemist obtained from the bark of the Lombardy poplar, 3.12 per cent.; from ash bark, 3.32; from elm bark, 2.7; from the white or European willow, 2.295; and from the Leicester willow, 6.86 per cent. of tanning principle. Lombardy poplar bark makes a light-brown colored leather, which acquires during the tanning a fragrant odor, somewhat resembling that which is given by birch bark. Elm bark is not much used in these countries for making leather, but it is utilized in this way in Norway, and the remarkable beauty of the glove leather of that country is attributed to the mode of tanning, which is done with elm bark. Willow bark also is restricted to the tanners of Northern Europe, although it is worked up occasionally with oak bark in British and other tan-yards. The Danish and Schoonian leather, much in request for the manufacture of gloves, owing to its peculiar and agreeable smell, is prepared with the bark of the white willow; in Russia, the tanner uses this material occasionally, but impregnates the leather subsequently with the empyreumatic oil of birch bark. The barks of all the cinchona species afford considerable quantities of tannin; still these are more valuable in pharmacy, owing to the alkaloids they yield, and, therefore, they are not resorted to for leather-making. Several other trees afford tannin, when their barks are submitted to the usual process, but they are rarely turned to any account.

Oak Bark.—The bark of the oak, has been for a long period extensively employed in tanning skins, and if other materials have been used, it still happens that, in Great Britain and Ireland at least, these have not been resorted to by preference, but rather from the scarcity of the staple article, oak bark, which seems to part with the tannin under those circumstances which best avail for its combination with the tissue of the skin, and thus for converting the latter into an article of prime quality. There are several varieties of oak, known as well in Europe as in America, all of which secrete tannin in their bark; but those which are valuable to the tanner are the different varieties of *quercus robur*, *quercus coccifera*, and sometimes the *quercus suber*, indigenous to Europe; and the *quercus falcata*, *quercus rubra*, *quercus tinctoria*, and *quercus prinus monticola*, indigenous to the American soil. The bark of the *quercus robur*—which term is applied to designate a group of closely allied species or varieties, and of which the *quercus pedunculata*, and *quercus sessiliflora*, form the two principal—is generally preferred by the tanner, with the exception of Norway and the North of Russia and some districts in France. In Norway, as already remarked, the birch and willow are resorted to, and in Russia and France the bark of other species of oak, the *quercus glomerata*, and *quercus coccifera*, are occasionally substituted. The latter variety,

known also as the kermes oak, is a tortuous branching shrub inhabiting the South of France, Portugal, and Spain. It grows to the height of three to four feet in close clumps, the roots interlacing one another, so that the soil, which might otherwise be washed away by the heavy rains, is retained. The bark of the root of this shrub, which is sometimes called coppice oak, is of a yellowish brown hue, and very rich in tannin. It is much in quest in France for tanning sole leather of a superior quality.

Barking of Trees.—In the foregoing pages are given the varied natural products which have been more or less employed, or offer advantages for tanning. The bark of the oak is, however, the most extensively consumed, and, therefore, much care is paid to its collection and harvesting. For a long time it was supposed that the rind of old oaks was more valuable for tanning than the product from younger wood; but experience is rectifying, or has done so, this mistake, for tanners have by a long course of working ascertained with certainty, what, through the labors of Sir HUMPHREY DAVY and others, has long been on record, that the bark of young trees is richer in tanning principle, than that of old ones; and, not only does the bark of the former offer this advantage, but the leather prepared with it is softer and whiter than what old bark produces, owing to the amount of coloring and extractive matter which they yield. Doubtless, the best age at which the trees should be barked, is from eighteen to twenty-five, or thirty years; but owing to the importance of the timber for building and other purposes, rarely are trees of this age felled in England or European countries. In France, however, they harvest the bark of oak of this age, but the wood is not turned to further use, excepting for the manufacture of charcoal, owing to the variety being unadapted for the builder. In France, too, the advantage may be gained of collecting the bark in spring, at a time when the sap is in full flow, and when there is most tannin contained in it; but in other countries, where the bark of the tree constitutes only an inferior secondary product compared with the wood, this season is not chosen, in consequence of the timber being cut when the sap is in active circulation and thus liable to decay. In England, Holland, and America, the period for stripping the bark is about June; but it varies according to the mildness of the winter and the spring. The operation of barking, is performed by cutting two circular bands round the trunk, at a distance of two, three, or more feet, then a longitudinal strip from one band to the other, loosening the bark at the upper, and stripping it off in bands towards the lower end. When stripped, the pieces are spread out to dry in beds, a shady site being preferred, care being taken to turn them occasionally, so as to prevent the beds heating. If the harvesting of the bark is not strictly attended to, considerable injury is sustained, not only in the loss of tannin, but more so in the kind of leather it affords in the pits. For the most part, or indeed in all cases, the bark should rest on hurdles elevated more or less from the ground in an inclined state, and the fragments ought never to be heaped together more than from twelve to eighteen inches in thickness. Provision ought to be made to protect the bark from the rain, and the whole

should be turned at least once a week till quite dry. After this it is usually stacked in larger rectangular heaps, and protected by thatch, if not by a roof, from rain or wet.

Quality of Barks.—It is important, that in regard to this article of so much value to the tanner, he should have some means of ascertaining its quality. By physical characters, the man of practice and experience will often form a good opinion in this respect, so as to decide between a good and bad quality of the same kind of bark; but this will not enable him to tell what amount of tannin it contains. Thus, if the bark has a whitish color exteriorly, and a reddish interiorly, and combines with these a dry, fragile, and clean fracture, and an astringent taste, the bark has been well harvested, and other properties being taken for granted, it is of good quality. So also when the epidermis and liber are thick, dry, and ligneous, with large crevices and a blackish aspect, it is deemed of an inferior quality, for the former characteristics indicate age, and the latter, that it has undergone a heating or fermenting change. There are other indications also from which persons acquainted with tanning materials form a judgment as to its goodness; it happens, however, that there are exceptions, so that an article presenting one or more of these appearances, may be of a first-rate quality, and make a good leather; but, under any circumstance, they will not lead the purchaser to the knowledge of the per centage of real tannin they yield. To attain to this end, a determination of the tannin must be made by chemical means, and even then the results are often only approximative.

Estimation of Tannin in Barks, et cetera.—Several methods have been devised for estimating the amount of tannin in barks and other products which are used in tanning, most of which are founded on the behavior of tannic acid with gelatin, and similar bodies; but mention will be made here only of those of DAVY, STEPHENS, and latterly, WARINGTON. The process of DAVY consists in treating three hundred and sixty grains of the powdered bark with a pint of boiling water, the vessel being frequently agitated during the digestion, which ought to last twenty-four hours. After filtering off the extract, it should be mixed with an equal volume of solution of jelly or isinglass, prepared by dissolving sixty grains of either of those substances in a pint of hot water. The precipitate of tanno-gelatin is then collected on a tared filter, exsiccated and weighed, and four-tenths of the entire taken as the proportion of tannin contained in it. Modern research has shown, however, that it is almost impossible to separate the precipitate by filtration from the liquid, so that at best this method is tedious; but it is inaccurate, inasmuch as the first portions which fall contain about fifty per cent. of tannin, which diminishes towards the end of the saturation. Sulphate of quinine, acidulated with a few drops of sulphuric acid, may be employed for precipitating the tannin from its solutions completely, and the deposit, unlike the gelatin compound, is constant in its composition. The tanner, however, in his yard, bases his operations on the indications of what is called the *barkometer*—an instrument like a hydrometer—and

according to the extent to which it sinks in the extract, so is the strength of the *ooze*, or tan-liquor estimated.

STEPHENS, to avoid the error to which DAVY's method is liable, proposed to estimate the tan by combining it directly with the cortical tissue, as in tanning, and determine the amount of the acquired weight. For this purpose, strips of the best ox hides, shaved as thinly as possible, are washed in water, thoroughly dried and weighed, then soaked in water a second time till they become soft and porous, and immersed in the extract of the sample of tan under examination, at a temperature of 90°. In the course of eight or ten hours, the whole of the tannin will have combined with the skin, so that after this period, by abstracting the strips, drying and weighing, noting the increase as the amount of tannin in the sample operated upon, the per centage in the bark may be calculated. This mode is likewise tedious, and fails to give satisfactory results.

WARINGTON proposes to estimate the tannin, not only in barks, but in all other astringent substances volumetrically, by determining what volume of a standard solution of gelatin is required to precipitate the tannin from the extract prepared from the sample submitted to examination. In preparing the test solution, the above chemist recommends the long staple

isinglass, as that is the most constant in its quality, and the least liable to undergo change. The solution is made of such a density, that a degree on the burette will represent one-tenth or one-fourth of a grain of tannin. Besides the preparation of the test liquor, the only other novelty in the operation, is the method employed for filtering off portions of the menstruum in order to determine whether the whole of the tannin be precipitated. As the passing of the liquor through bibulous paper, would not afford a clear filtrate, a piece of glass tubing, a foot in length, and half an inch in internal diameter, was selected; into the lower extremity a piece of wet sponge was introduced, and when it was desired to abstract a portion of clear liquid from the assay, in order to test if further precipitation took place, the sponge end of the tube was submerged, and the fluid filtered by ascending through the sponge. Part of the clear menstruum thus obtained, was transferred to a test tube, and a drop of the test solution added, till the point of saturation had been accurately arrived at. By this method, which is as applicable to the substances rich in tannin as to bark, accuracy and expedition are secured.

The annexed table, from MORFIT, indicates the per centage of tannic acid contained in the various substances specified:—

TABLE OF THE AVERAGE QUANTITY OF TANNIN IN DIFFERENT SUBSTANCES.

Substance.	Per centage of tannin	Authority.
Catechu—Bombay,.....	55.0	Davy.
“ —Bengal,.....	44.0	“
Ratany root,.....	42.6	Peschier.
“	38.3	C. G. Gmelin.

Winter's bark,	9.0	Henry.

To render any of the foregoing materials suitable for the present operations of the tanner, it is necessary to bring them into a minute state of division, in order that by the treatment to which they are subjected, they may the more quickly yield up their tannin.

Fig. 342.

With the exception of the inspissated juices, this condition is gained by grinding or cutting machines which reduce the roots, branches, or barks, to a fine powder.

Fig. 343.

Numerous kinds of mechanical adaptations have been introduced into this department, varying in simplicity from the old head-stone rollers, to very intricate ar-

rangements. It would require too much space to give even a curt description of these; suffice it then that the principles on which they are constructed may be inferred from the machines described here :—

FARCOT'S bark-cutting machine, extensively used in France, is shown in elevated section and plan in Figs. 342 and 343, in which AA' are two fluted cylinders, which supply the bark previously spread upon the table, *a*, having a raised ledge, *h*, to the cutting apparatus. This is composed of two parallel circles, fixed upon a common axis, *c*, having steel plates or knives, *BB*, screwed upon them, and which are disposed in the form of a helice or spiral. On one end of the axis, *c*, is the fly-wheel, *s*, and drum, *D*, which receives the movement or power by a strap that connects it with the main shaft of the engine; the other end has a pinion, *i*, which gears into a toothed wheel, *J*, on the axis of the

Fig. 344.

fluted cylinder, *A*, and by means of another smaller one acting upon *E*, on the axis of *A*, the motion is likewise transmitted to the latter. By the levers, *FF*, and a weight, *G*, the two cylinders, *AA'*, are regulated to any required proximity. Inside the fluted cylinders is a longitudinal piece of steel, *C*, which delivers the bark to the revolving knives, and at the

same time acts by its sharp edge as a shears towards the cutting knives. The cylinder which carries the cutting knives makes about one hundred and thirty revolutions per minute, as also the feeding cylinders; and the quantity of bark cut averages one thousand six hundred pounds per hour.

The chopped bark is then passed to a mill for reducing it still further, and which is shown in Fig. 344. This machine is on the principle of WELDON's bark-grinding mill, introduced so far back as 1797. In this figure, A is a conical drum of iron on the end of the shaft, D, which forms its axis, inclosed in the cast-iron hopper, B B, where the coarse bark is deposited. This hopper is firmly secured by screws to a flange, which runs all round the framework, *vv*, as shown at *aa*. In the top of the exterior is a cross beam secured by screws, and having a socket in the middle part through which the axis of the drum passes. The lower part of this shaft rests and turns upon a bed, C, upon the stage, T, and regulated so as to have the cone, A, in position, by the side and bottom screws, *a'a'* and *b*. The inner face of the hopper, B, which is in close contact with the revolving cone, is, like the latter, serrated or grooved, so that the bark passing down is more minutely sundered. Fig. 345 shows the position of the two cutting surfaces with respect to one another.

Fig. 345.

The central drum makes twenty-five revolutions per minute, and in the course of twenty-four hours grinds about eight thousand six hundred pounds of bark. The cutting machine already described is capable of supplying three grinding mills.

Another grinding mill, very much used in America, where it is known as WILTZE's or CATSKILL's, is shown in Fig. 346. This in principle is the same as WELDON's, only that instead of grooves an arrangement of sharp-edged teeth, both in the inclosed bell and hopper, is employed. As the bell turns by the power exercised upon the shaft, the teeth in the former,

Fig. 346.

revolving, also react on the principle of the shears with those in the interior of the case, and the bark is very finely and rapidly reduced. Before the matter is submitted to this machine, it is broken by passing it into another hopper adjacent to the former, in which there

is a sharp-toothed hoop or curb, and which divides the bark into pieces. It is moved at the rate of thirty to forty revolutions per minute, whilst the grinding machine may travel at the rate of one hundred and fifty. With this speed, communicated by a ten horsepower engine, it will grind from one to two cords per hour. The bark is cut short, without being reduced to flour, and thus it is more readily exhausted; there is also the additional advantage that, should the bark be moist, it does not become clogged like others.

THE SKINS OR HIDES.—The next object of attention in the preparation of leather, is the hides or skins of the animals. Three classes are specified in commerce; the term *hide* is applied to the skin of the larger and full-grown beasts; *kips* are the skins of the younger animals of the same class; and *skin* indicates the hides of the sheep, goat, kid, and the like. The term *kip* is qualified by the size of the skins. Generally speaking, the skins which are converted into leather, are those of oxen, cows, and calves, of the sheep, the goat and their young, of the horse, the pig, the dog, and a few others; but by far the most extensively worked, as well as the more important, are ox, cow, and horse hides, kips, calf, and seal skins. Considerable difference is observed in the thickness and quality of the skins of various animals, even of those of the same class, owing to circumstances connected with the food, age, variety of breed, the state of health, and even the period of the year when they are slaughtered. Thus, large oxen are well known to afford hides which are tanned into thicker and heavier leather than bulls or cows, especially if the latter be old, and have had several calves. Bull hides are coarser grained, and thinner in the back than those of oxen and heifers, or young cows, but much denser in the neck, and parts of the belly. It would also appear that when cows have repeatedly calved, the skin becomes distended and thinner, and does not, therefore, afford as heavy a sole leather as that of younger beasts. Again, hides of animals dying in a state of disease, are found to be much inferior to those of healthy ones of the same class, although the apparent difference is not very marked before tanning. No very definite *criteria* are known, to guide the purchaser in distinguishing the quality of hides and skins. If the hide be thin, flabby, soft, and will not bear handling, then such a one will not make good leather; but should it present the opposite qualities, it may be confidently expected to be a good article. It has been remarked of sheep, that the finer-wooled variety have inferior skins; also that the skin gains in thickness and quality, considerably, in the course of a few days after shearing.

Ox Hides.—Under this head may be enumerated the skins of *oxen, cows, buffaloes, and calves*. In Great Britain and Ireland, the market draws, in the first place, upon the home produce; these are usually vended in the *green* or fresh state. They are obtained from the extensive *abattoirs* generally found in large towns, and local butchers throughout the country. But besides these, considerable numbers are imported from other countries, especially from South America, the East and West Indies, and the Cape of Good Hope. The trade carried on between Great Britain and the South American

ports in hides, though averaging a million annually, is only a fraction of what sprung up of late years between that country and other European nations, such as France, Belgium, Austria, and Greece. The animals which roam along the Pampas and Llanos, or great plains, in herds of vast numbers, are, in addition to those owned by the extensive cattle owners or *hateros*, the stock whence this vast quantity is annually derived. They are imported in the dry state, and salted, and produce a very good sole leather. It should be remarked, however, that the hides from beasts inhabiting the extreme Southern latitudes, are not suited for tanning so well as those from the temperate and Northern parts of the globe. The *green* or fresh hides of the home market always rate higher than other sorts, owing, perhaps, to the fact that they do not require so much labor as the imported dry kinds; still, in consequence of the amount of water they contain, they prove to be much dearer than the others; for allowing that for the production of one hundred pounds of leather, seventy-five pounds of dry hide are requisite, the equivalent of this of salted hides, would average a hundred and fifty pounds, and a hundred and eighty-five of green or market hides. Heavy hides are converted into sole, belt, and harness leather, also for carriage coverings, and the smaller and lighter kinds are made into leather much used for *skirtings*, and for enamelling. That which is used for ladies' shoes, and for bridle-leather, undergoes a bleaching process, termed *fair finish*. Hides from the West coast of Africa, make good upper leather, but are much employed in their raw state for trunk covering.

Calves' skins and kips of home produce are of very superior quality, and produce a leather, when made with good oak bark, very extensively worked into uppers of shoes and boot fronts. In France, where the calf-skin leather has been reputed for its excellence, they are taken off the animals when five or six months old. Kips are imported from the East Indies, Buenos Ayres, and Monte Video; those from the former place are dried and salted, or merely exsiccated, and from the latter places, they come simply salted. The countries adjoining the Baltic, more especially St. Petersburg, send here a good many; but owing to the animals being slaughtered when young, they are, properly speaking, skins. Many of them, however, as well as some imported from other countries, belonged to small, but full-grown animals, and are, properly speaking, hides. The lesser and inferior kinds of kips and calf-skins are tanned for bookbinders' use, for gloves, and the manufacture of ladies' boots and shoes. Buffalo hides imported from the East Indies, are tanned like ox hides, but they make an inferior quality of sole leather. The American Indians prepare these into robes, the hair being retained on them. When tanned in a particular way with oil, they constitute what is termed *buff belt-leather*, which is superior to the similar article made of cow-hides.

Horse Hides.—The skins of these most useful animals are much inferior to those of oxen in thickness, texture, and strength, and, consequently, they are never prepared with the view of making *sole* leather, though the better quality is used when tanned for uppers. The chief

consumption is, however, as cordovan, or enamelled leather, the hides being split by machinery to reduce them to the adapted thinness. Horse hides are likewise made into tawed, white, or alum leather, and are in this state used as aprons for certain classes of mechanics, and as thongs for the manufacture of the commoner kinds of whips, and for sewing common harness. A considerable number of horse hides is annually imported from South America, sometimes as many as one hundred and ninety or two hundred thousand. The imported hides are much superior to those which find their way to the home market, on account of the latter belonging generally to old and worn-out animals, while the former have been flayed from the captured wild horses of the pampas, lying between the chains of the Andes. Ass and mule hides, tanned and so prepared serve for the manufacture of scabbards; the leather is called *shagreen* or *shagri*.

Sheep Skins.—The home supply is very extensive; and although they are capable of making only a spongy weak leather, the uses to which they are devoted are various, and their manufacture gives employment to numerous hands. Tanned with bark they constitute bazils, and are used for making slippers, and as bellows-leather; but when prepared with alum and salt, or with oil, white leather, much employed for aprons and by druggists, chamois leather result. A good many are split, the upper or grain side being tanned with sumac and dyed, then worked up as *skiver*, *roan*, and *morocco*, into pocket-books, hat-linings, and the under portion being made into white leather, and used very much by the chemist; but it is much the more general practice to reserve lamb skins for the latter purpose. Sheep skins are sometimes tanned with the wool adhering to them, and made into mats. The principal seats for the dressing and dyeing of sheep skins in England, are Bermondsey, Leeds, and Manchester; from these places they are exported to various parts of Germany, South America, and the United States; but the exports to the latter country are only partially prepared and salted. A large number of the skins of a particular breed of sheep is imported into Great Britain, and a similar variety is brought into this country, and likewise into France, from Asia Minor. In the latter country a considerable trade rises from the preparation of lamb skins for ladies'-glove leather, for linings of morning gowns, for slippers, and for winter gloves. In the hides from Asia Minor the wool is kept for the purpose of retaining the warmth. Considerable difference may be observed in the quality of lamb skins; those from the animals killed shortly after being born are possessed of a very fine grain, and take a very uniform dye; the same qualities are, in a great measure, retained by the skins till a month old, but from this period they begin to deteriorate. In the Southern parts of France and in Italy great numbers of lambs are killed, averaging four weeks old, and the leather prepared and employed as a substitute for kid leather. Not less than one million four hundred thousand of these skins are annually imported to Great Britain for the use of the glover.

Goat Skins.—A very large trade is carried on in Great Britain and Ireland in goat skins, and the tanned

and prepared leather they yield. In the latter country a number of native skins is used, but the British market is supplied almost entirely by imported goods, more especially from Switzerland and the valley of the Rhine, from Magadore, the Cape, and the East Indies. Those from Switzerland—Swiss skins—are more esteemed, because they possess a close, fine, and equal grain, which enables the dyer to give them a brilliant and permanent hue; the leather is also stronger, and wears better than any other manufactured from goat skins. On an average about one hundred thousand are imported annually, and fabricated into morocco for the demands of the various branches of trade. Mogadore skins are made into a kind of black morocco leather, which still goes by the title of Spanish leather or cordovan, in consequence of the first supplies of this article being obtained from Spain and the Cordova, where the Moors originally brought the manufacture to great perfection. The sound skins which arrive from the Cape of Good Hope are much larger, and superior in strength and thickness, to any other variety. East India skins are small and light, and are generally converted into leather chiefly used for ladies' shoes and upholstery. Those from Mexico, known in the American market as *Tampico* skins, bear a very high character. Compared with sheep skins, those of goats are much superior in texture, strength, and durability. Goat skins are occasionally prepared so as to imitate chamois leather, and applied to most purposes to which the latter is adapted, and likewise with the hair on, and used for matting. Kid skins, manufactured into leather, are most extensively consumed by the glover, also for shoes, binding leather, and the like. Great numbers are produced in Ireland, the South of France, Switzerland, Italy, and other European countries. Those of France have the greatest repute; the Irish skins are likewise highly esteemed. After the animal begins to feed upon herbage, the skin invariably loses in delicacy of texture, and, therefore, becomes unsuited for the finest gloves.

Deer Skins.—A considerable number of these skins is manufactured into chamois leather, particularly in the United States, and also into glove leather. The preparation of this kind of leather in Great Britain and Ireland is very limited.

Hog or Pig Skins.—In Scotland, the swine are skinned; the skins are tanned, and constitute a very porous, light, but nevertheless very tough and durable leather. It is largely used by harness-makers and for saddle seats. The practice of skinning pigs is followed on the Continent, where the hide is dressed with the hair on, and used to cover portmanteaus, knapsacks, *et cetera*.

Seal Skins.—Of these a great quantity is imported yearly into Great Britain, and manufactured into upper and varnished leather. They are obtained from the animals captured along the shores of North America, from Newfoundland to the Arctic ocean, for their oil. A large portion of the supply comes from the coast of Norway. The skin of the seal is light, but of a close texture, and, when properly tanned, yields a leather which has greater strength, in proportion to its weight, than any other variety. Seal skin is usually made into

black enamelled leather for ladies' shoes, the stronger sorts being employed for the upper part of hunting and riding boots, and knapsacks. Many skins are merely dressed and converted into materials for caps and fur clothing.

Porpoise Skins.—The skins of the white porpoise have been tanned in Canada, and the leather is said to be soft, strong, and possessed of a beautiful finish.

Hippopotamus Hides.—About one hundred of these skins are annually imported from the South of Africa, and are tanned with oak. The hide, originally of great thickness, assumes the appearance of boards after being tanned. The only use which appears to be made of them, are implements used for beetling in washing and bleaching cotton and linen goods.

PREPARATION OF THE HIDES.—The tanner, previous to submitting the hides, skins, or kips, to the true tanning process, is under the necessity of subjecting them to one or more preliminary operations, with the view of removing dirt, particles of flesh, and in most cases the hair and epidermis; and the manner in which these are effected is of great importance, as much of the success of the subsequent process, and, consequently, of the quality of the leather, depends upon it.

Cleansing.—The hides which have been recently taken from the carcass of the animal require but very little labor to purify them from any filth which may remain attached to them, unless, indeed, as is said to be sometimes the case, they are wantonly saturated with such matters in order that they may weigh heavier. Sometimes, however, such *green* or *fresh* hides, as they are called, when they cannot be immediately disposed of to the tanner, or when the latter does not intend to submit them at once to the processes by which they may be made into leather, are salted to prevent putrefaction. When the hide has to remain for a period of a week, four or five pounds of coarse salt are used to preserve it; if a month, double this quantity is deemed requisite. Foreign hides—such as those from South America—receive more than the above quantity; in some instances as much as twenty pounds of salt per hide are used, according to their size and the season, but the average for foreign hides is about fifteen. All these matters must be separated by steeping and washing; and hence one of the absolute requirements of a tannery is a profusion of water. Green hides are steeped in water during a period of one to twelve hours, according to the quantity of blood and dirt they hold, at the end of which time they must be thoroughly rinsed before removal. In many cases much greater pains must be taken, such as repeated scrapings of the hide with a blunt tool on the beam or support, trappings in the water buckings, *et cetera*. If a current of water is available, much labor is spared by fastening the hides to a rack fixed in the face of the stream, for the friction of the water will detach the impurities without the aid of much mechanical labor. When dried hides, or such as are salted and dried, are treated, the difficulties are much greater, since a longer period and more time is required to soften and bring them into the condition of fresh ones. With these the soakings, trappings with the feet, handlings—that is, the removal from the water

or steep—and scrapings are multiplied before they attain the softness and purity of clean fresh ones. In large establishments the mechanical labor required is executed by a kind of mill, similar to that for fulling cloth, wherein the hides are exposed to the continued action of two heavy stocks, which squeeze out the slimy matter and dirt that might induce a putrefactive fermentation. The immersion and handling even in this case require to be alternated with the action of the machine; and it is necessary to remark that where vats or tanks are used, the water should be frequently renewed, otherwise, if the contents happen to get stale or overcharged with the slimy extract from the hides, and the time of submersion be prolonged, there is danger of putrefaction, and, therefore, of injury to the skins. Where only water is employed for the above purpose, it is necessary to keep in view the quality of this liquid, irrespective of the change which it undergoes by saturation with the nitrogenous matters, dirt, *et cetera*, from the hides. When very calcareous, its cleansing qualities are less effective than when the water is *soft*; but, independently of this, it is believed that *hard* water affects the hides in another way, by which their softness and porosity are injured, owing to the fatty and other matters which may be in an incipient state of decomposition, forming combinations with the earthy bases which fix themselves in the skin.

In many parts of France and Belgium, they employ a weak solution of lime to assist in cleansing and freshening the hides, with the view, at the same time, of rendering the succeeding operations of depilation and tanning more easy and efficacious.

Depilation.—After the thorough softening and cleansing of the hides, they are next submitted to a further immersion in baths or tanks with compounds which effect the solution of the cellular matter in which the hair is rooted, or are otherwise exposed to the action of agents which operate towards the same end. A variety of methods are practised by tanners for the solution or softening of the matter which binds the epidermis and hair to the true cutis, or that portion of the skin that enters into the formation of leather, with the view to their removal. The most important of these are the *liming* process, the *sweating* or *fermentative process*, the *rhusma* and gas lime processes; and latterly, in America, the *cold sweating* mode has been introduced with success.

By Liming.—Of these processes the *liming* is by far the oldest, and is still very extensively adopted, but with greater caution than in former times. In its action it is not so quick as certain other agents, necessitates much future labor, and frequently is the cause of injury to the leather; still, probably from its cheapness and the effect of custom, it is more resorted to than any other. Generally speaking, it is now used in the form of a semi-liquid or milk, formed by agitating a certain quantity of it with a given body of water—about eight bushels to one hundred and fifty gallons. The liming is carried on in a series of pits or tanks, sunk in the floor of the liming house; these are built of bricks or masonry, and well cemented, and have an outlet at the bottom for the purpose of drawing off the fluid contents when necessary. Their dimensions

vary according to the requirements of the establishment, and the number of skins to be operated upon at once. In some parts, as in France and Belgium, well bound wooden tubs are preferred. The number of these varies from five to twelve, and the solution in them is so arranged, that there is a regular increasing gradation of density from the first to the last, even where the larger number is taken advantage of. The first of these, called usually the *dead vat*, contains very little caustic lime, and this is the one to which the hides after washing are exposed, in commencing the operation. Here they remain for one, two, or three days, according to circumstances, and during this period they receive a handling at regular intervals, some twice, and others three times a-day. This handling merely consists in taking the skins out of the pit or tub, and laying them on a plank or inclined board near the tank, and introducing them again. Before the re-introduction, the contents of the tank are well agitated, with a view to distribute any undissolved quick-lime through the liquid, so that there be no partial or undue effect exercised on the skins. The workmen likewise contrive to spread out the latter in the vat as much as possible, and so every part has the same exposure to the lime. In the dead vat, however, there is left very little if any quick-lime undissolved. After spending the allotted time in the first vat, they are transferred to the second, which contains a stronger liquid, or more lime, and left in this, with occasional overhauling, for a few days, after which they are put into the third, and so on till the hides ultimately arrive at the last vat, which contains the fresh lime. In operating in this rotation the dead vat of one batch of hides becomes the *live* one of the next, and so on in succession. The time which skins take for thorough liming, varies according to their weight and texture. Thus the lighter skins, as of the sheep, are sufficiently acted upon in three to five days, but ox hides, kips, and calf-skins, require two to three weeks, according to the season. Formerly the process of depilation extended over a period of three to fifteen months, and even eighteen, the hides being steeped in the weak lime vats a considerable part of this time, but such procedure is now entirely relinquished. In many parts of the Continent, however, the operations preparatory and conducive to the depilation last two and three months; but in these cases the skins are partly swelled, so that, for this special treatment, they do not require so much attention in the succeeding stages. The quantity of lime which is used by the different tanners is somewhat various, and dependent upon the size of the hides, but the average is from eighteen to twenty-four gallons of freshly-burned fat lime—three to four cubic feet measure—for a hundred hides of average size. The lime is permitted to slack in the strong or live vat, and afterwards stirred about with a wooden spatula, to distribute it equally in the liquid.

When the epidermis is sufficiently softened it is detached, together with the hair on the *beam*. This is an arched wooden or stone bench—Fig. 347—upon which the hide is laid, with the flesh side inwards, and the hair removed by the *scraping knife*, shown in Fig. 348. After the separation of the hair and epi-

dermis, the loose fragments of skin are pared off, as likewise the flesh and fatty matters adhering to the

Fig. 347.

reverse side—such fleshings being economized in the preparation of glue. The implement used for the latter purpose is a long, straight knife, having a sharp edge.

Fig. 348.

Fig. 349. After the last operation, it is necessary to submit the hides to thorough rinsing in the stream or vats, in order to remove all uncleanness, lime, et

Fig. 349.

cetera, as much as possible. It often happens that the hides present inequalities as to thickness and the like, and to reduce them to average homogeneity, they are treated with the smoothing or polishing stone, represented in Fig. 350. This tool is of sandstone, interiorly moulded, so as to lie parallel upon the beam, fixed to a piece of wood, and furnished with handles,

Fig. 350.

with which the hide is rubbed, to bring the part to an equal thickness as nearly as possible. This operation is not so much practised by English as by continental tanners. By repeated scrapings in this way with the knives and stone, alternated with steepings and washings, the dirt, hair, fleshy parts, and lime are removed as effectually as possible, previous to the true tanning operation. In the large English tanneries the scraping and fleshing of the hides are executed by mechanical contrivances, and so the manual labour is greatly diminished. Machines for this and other purposes have been constructed by several, among others by POOLE, PLANT, and WOODWORTH.

Bating.—With respect to the removal of lime from the skin, it has been found that no amount of scraping and rinsing is capable of making a perfect separation, a portion of the earth being retained in the pores of the skin, combined with, perhaps, some of the decomposing tissue, and with the grease and fat of the hide, as a lime soap. These combinations, if not altered and

removed, obstruct the union of the tannic acid with the gelatinous fibre of the skin, and not only this, but they communicate a rigidity to the leather which excludes it from such applications as require a soft, tough, and pliable material. Several plans are employed to remedy this defect. The old method is that which is known as the *bate*, or *grainer*, that is, a menstruum prepared by macerating the excrements of pigeons, pen-fowls, and of dogs, in water, and immersing the scraped and clean skins in it for a certain period, when, it is stated, the lime is separated by a chemical decomposition that takes place and renders it soluble. The proportions employed are from ten to twelve gallons of the fresh dung to one hundred, or less if they be large skins; and the time of steeping stretches over ten days in ordinary weather, but less time is required if the liquid be warmer. In this treatment, likewise, the repeated handling and scraping on the beam are resorted to. Investigation has shown that the above matters contain an ammoniacal chloride that parts with its chlorine on coming in contact with the lime, and so gives rise to a soluble combination of this base—chloride of calcium—that may be readily abstracted by water. That this disgusting method should still continue to be so extensively practised is disgraceful to modern science. It is stated, that in London alone not less than five thousand pounds are annually expended in collecting and purchasing the above materials, for the sole use of the tanners of the capital and its suburbs.

Although this method of *bating* the hides is tolerably effective, yet it is well known to be attended with serious disadvantages, not the least of which is the putrefaction of the *bate* that is going on during the steeping, and which injures the hides by acting upon the tissue of the skin, reducing its weight in the first instance, and in the second, rendering it incapable of yielding the quality of leather it would doubtless produce, did the above change not occur. Taking the hint from the action of the alkaline chloride in this case, some tanners have attempted to prevent the putrefaction induced by the bating with excrements by avoiding its use altogether, using hydrochloric acid in a diluted state as a substitute. The innovation has not yet become very general in England, although many tanners, especially in Paris, are reported to have practised it successfully, the object of the expulsion of the lime being satisfactorily gained by it, and in addition to this, the swelling of the hides also. Sulphuric acid has likewise been proposed as a substitute for the *bate*, but the effect of this is not so powerful as that of the acid already mentioned, since it constitutes with the lime a very insoluble compound. The acid is, however, almost always resorted to for *raising* or swelling the skins, preparatory to submitting them to the tan-pits. MACBRIDE in 1774 was the first who showed that it possessed this property. TURNBULL introduced the use of saccharine liquids for removing the last portions of lime from the hides, as well as for softening the hair and cuticle. Four or five pounds of coarse sugar or treacle dissolved in sixty to seventy gallons of water, constitute the bath. The sugar in this process forms a soluble saccharate of lime, which is removed by

soaking and rinsings. A new process, in connection with others, for the purpose of facilitating tanning and improving the leather, was patented in 1841 by WARINGTON. It consists in employing carbonate of ammonia instead of the usual bate for the graining of the skins; but although this salt converts the lime into a neutral compound, it does not remove it, and consequently, the flexibility and softness of the skin must suffer.

Depilation by Acids.—Besides these methods, by which the influence of the lime on the skin is counteracted, others are employed which dispense with it in the first instance. Acid liquors have long been known to operate upon the roots of the hair and epidermis, so as to detach them from the skin. The Calmuck-Tartars employed a bath of sour-milk for this purpose, and in Paris the same agent is adopted at the present time. Another menstruum, obtained by the fermentation of barley or rye meal, was once very extensively used as a steep for the hides for separating the hair. Here, together with the fermentation, the active body was acetic acid resulting from the latter. This, in common with other acids, such as sulphuric, hydrochloric, oxalic, *et cetera*, operate so as to soften the epidermis and hair, to an extent sufficient to enable the scraping process to cleanse the skin from them. Tanners urge, however, that by their use the skins are swelled to such an undue extent, as almost to render it impossible to prepare good compact leather from them. The weak vegetal acids, however, are not excluded from practice, more especially in France, Belgium, and parts of Germany. Many of the Paris tanners submit the hides, after they have been soaked in water, washed, and fleshed, to a number of acid vats, in a way analogous to the liming. Generally, the series of baths consists of five, which from the first to the last increase in power and efficacy; the first is usually intended to cleanse the hides, the second to soften the hair and epidermis for the depilation, and the other three to swell and give body to the skins. This operation, which is called the *white dressing*, requires a period of five weeks in the summer, and six in the winter season. The quantity of farinaceous matter which is taken varies at different establishments; in some cases one hundred and forty-five pounds of barley-meal, and in others, one hundred and fifty or sixty are employed. The dressing is generally made by leavening one-tenth or one-fifteenth of the bulk till it becomes sufficiently sour; it is then softened with hot water, and after the whole has become a thick homogeneous fluid, free from lumps, it is added to the remaining quantity of the meal in the vat, and tepid water in sufficient quantity poured in to fill the vessel. In some cases yeast is added to quicken the fermentation. Eight or nine hides are worked in each vat, and as in the lime process, the weak or first vat passes in succession from one to the other in rotation. The final vat is composed with sixty pounds of meal leavened and thinned with water, and left to develop acetic acid for fifteen days. In all of these operations the handling and working the hides on the beam at regular intervals are indispensable.

By Sweating.—The depilation is effected at the pre-

sent day by many English and continental tanners, more especially the latter, by what is known as the *sweating process*. Various means are adopted, but the principle common to all is the softening of the epidermis, by fermentation, or putrefaction. In Paris and other parts of France, one-half the hide is sprinkled with some chloride of sodium, and the other half lapped over it, with the view of arresting the effect of the putrefaction which succeeds from injuring the tissue of the skin. Several hides are then piled one upon another in a pit or other convenient place, and left till an incipient odor of ammonia is observed. This is a sign that putrefaction has commenced, and, therefore, that the hides are approaching to a state in which they readily part with the hair. As the fermentation thus excited would be very deleterious to the leather-making portion of the hide, too great caution cannot be exercised in order to arrest the action as soon as the hair is softened. With this view, the hides should be examined once or twice a day, refolded and piled again, till it is discovered that the hair will readily yield. The same result is attained, without the precaution of adding salt, in Germany and some parts of Great Britain, by simply piling the hides upon one another in a pit. The moisture and circulation of the air acting upon the nitrogenous matters—blood, sweat, and other impurities—readily augment the heat of the whole mass; and incipient putrefaction, recognizable by the evolution of ammonia, follows. It is necessary to examine the hides frequently, lest the action should prove injurious. In many instances they are piled between layers of stable dung in a heap, and the whole covered with the same material, till the hair becomes detached, care being taken, however, to examine the hides every twenty-four hours or less.

Steam and heated vapors have also been tried as agents for removing the hair from the skin. M. DELLUT was the first to suggest the use of steam, and his method was carried into effect in several French tanneries. The hides are suspended in an airtight chamber of suitable dimensions, and which is furnished with a perforated, false, or second flooring. Steam is introduced beneath the perforated flooring, and ascends among the hides, through the small orifices, so as to keep the interior of the chamber at 68° to 80°, but not beyond this; for, in the event of the temperature becoming elevated, the gelatinous matter of the skins would more or less enter into solution with the condensed steam on them, and consequently, would afford a less weighty leather. When due attention has been paid to the operation, the hair and epidermis becomes sufficiently softened in twenty-four hours to be removed with the hairing knife. Compared with the putrefactive sweating process, this method is a decided improvement, as the liability to injury is very much diminished.

By Cold Sweating.—In America, especially in New York, New Hampshire, and in many parts of the Northern division of Pennsylvania, a process is in general use, called the *cold sweating*, by which the hair can be removed, and a yield of leather estimated at seventy to eighty per cent. acquired; whilst, by other means employed, such as by steam and lime depilation, not more than thirty to forty per cent. of the dry hides are retained

as leather. Besides this very material gain, another advantage follows, namely, that the laborious cleansing and fulling required in the other modes, is unnecessary; and consequently, the hides retain their natural density, a condition which very much improves the quality of the leather. The operations by which this is effected, are thus stated in a foreign journal:—

First, a vault should be prepared for the reception of the hides; this, for convenience sake, should be twelve feet long, the same in depth, and ten feet wide. The walls may be of stone, brick, or a planked frame. There should be one alley or vestibule for entrance, not less than six feet long, having a door at each end, the outer being made double and filled in with tan, to prevent the communication of warm dry air from without. A ventiduct made of plank, ten or twelve inches square, should extend from the bottom of the vault to the distance of three or four rods, and should be fixed not less than three or four feet below the surface of the ground. This channel serves both as a drain for discharging the water of the vault, and for admitting cold damp air to supply the place of that which has become rarified, so that a current is thus kept up through the ventilator at the top of the vault. The ridge of the roof may be on a level with the ground, and on it, extending its whole length, are set up edgewise two planks two inches apart. The space between these is to be left open, but the remainder of the roof may be covered with earth to the depth of a yard. Such covering is intended to preserve a low temperature in the pit, so that the hides may unhair without tainting. Spring water should be conducted, either in pipes or logs, around the angles formed by the ceiling with the walls of the vault; and from these conduits the fluid should be allowed to flow in minute jets, so as to form a spray, or else to raise a mist or vapor, so as to saturate the atmosphere of the vault with watery vapor. This arrangement keeps the temperature of the vault much under that of spring water itself, which usually stands at 50°, owing to the heat rendered latent by the evaporation. Three bars furnished with iron hooks, at intervals of three inches, are laid longitudinally and equidistant near the ceiling, and upon them the hides are suspended. Before hanging up the hides, they are soaked as for breaking, and then suspended from the butts in a way that they remain fully open. In the course of a few days, when the hair begins to loosen on the upper parts, they are taken down, and the middle bar being raised, they are again suspended by the other end, and left so till the hair easily separates. The hides should not be broken till they are ready to unhair. In a good vault, where the heat is maintained between 44° and 56°, above which it should never be allowed to rise, and where there is a free circulation of damp air, the hides generally require from six to twelve days. If the temperature falls below 44°, the ventilator should be partially closed; but if it rises above 56°, cold damp air must be forced in, or a larger volume of spring water thrown into the pit.

MORFIT states, that the hides carried carefully through this process are, when received by the tanner from the beamsman's hands, free from all extraneous matter, and retain all their gelatin, albumen, and fibrin

in an unimpaired state; and that it is not a fermentative change that produces the unhairing, because there is no ammonia generated. The effect is owing to the softening action of the absorbed vapor upon the epidermis, in conjunction with a swelling or distention of the roots of the hair, and tissue of the skin immediately underlaying them. Should these advantages be found, upon trial, attendant upon this simple and quite feasible method, it would undoubtedly be for the interest of tanners to adopt it, as not only does it require less labor, but the requirements in the shape of pits and water are still less than for the systems practised on this side the Atlantic, leaving the consideration of the great gain in the amount of leather out of the question; and which, of course, is its most powerful recommendation.

By Rhysma.—WARINGTON recommends a solution of carbonate of soda for unhairing the hides, but the effect is not so rapid as when the alkali is in the caustic state. The same chemist, in attempting to depilate hides by the use of *rhysma*, the long-known mixture of caustic lime and orpiment, or tersulphide of arsenic, discovered that the active agent was sulphide of calcium, formed by the decomposition of the arsenical compound in the presence of that base, and that *the arsenic* was without effect in the operation. He therefore tried the action of sulphide of calcium *per se*, and found that it acted so promptly, that only from twenty-four to thirty-six hours were required to soften the epidermis, and loosen the hair.

RAISING OR SWELLING.—After the removal of the hair and epidermis, and the bating, in case of hides intended as upper or pliable leather, it is necessary, to submit the *pell*, as the depurated unhaird skin is commonly called, to a further operation, in order to distend its cellular organs, with the view of enabling it the more readily to combine with the tannin. In England, sulphuric acid, in the ratio of one part of acid to a thousand of water, is the agent usually employed for this purpose; but in some cases immersion for a limited period in the spent tan-liquor, wherein a certain quantity of gallic and other acids have been developed, is substituted, and even this treatment is abandoned by many, a weak tanning liquor being preferred. This is especially the case in France, where a prejudice exists against the use of sulphuric acid, founded on the opinion that it destroys many of the good qualities of the leather. When sulphuric acid is used, the swelling or raising is sufficiently executed by twenty-four hours' immersion in the bath. When kips and skins are under operation, the raising is done partly during the liming and partly by the *bating*, to which they are afterwards submitted. Allusion has already been made to the mode practised with excrements; but besides this, the same end—the removal of any residuary lime—is attained by the employment of barley meal, made into a sour liquor. For one hundred pounds of dry skin, fifty pounds of coarsely-ground barley meal, and five or six pounds of soured dough are taken, the whole being intimately distributed in the water. Lactic fermentation follows, and the acids generated form soluble salts with the lime in the skins, when the latter are immersed in the liquor, and the succeeding washing removes them. This bath is termed

the *white* bate, to distinguish it from the *red* bate, or the aqueous washings of old used bark or tan. With this reddish brown liquid a number of vats are filled, the solution in the first being diluted so as to give them a gradation of strength. Before submitting the washed and unhaired skins to the series, they are steeped for a few days in summer, but a longer time—four or five days—in winter, in clean water, which is renewed every day, whilst the skins are left to drain for two or three hours. After this they are submitted to the first and weakest vat of the red bate, and after spending some time in it, they are transferred to the next, and so on, till they come to the last. During these operations the practice is to handle the skins morning and evening, leaving them to drain about three hours, whilst they are passing through the weak baths; but once a-day when they arrive at the stronger ones. Sometimes, in this way of working, the final bath are a solution of fresh tan, more or less concentrated, according to the views of the tanner. When the baths are rather concentrated, the period occupied in swelling by this method varies from a fortnight to three weeks.

The finishing of the *raising* is effected occasionally with strong tan-juice, which has been mixed by agitation with about four pounds of sulphuric acid. Eight or ten hides being submitted to this bath, they are taken out the first day twice, and permitted to soak or drain for two hours, the second day once, the same time being allowed for draining. In the morning of the third day they are transferred to another, composed of the densest tan-liquor, mixed with the same quantity of sulphuric acid as the foregoing. Whilst here, the hides are handled once a day, being allowed to drain at each handling one hour. About three days suffice to give them the necessary finish.

The red bate is regarded as being by far the best means in use, notwithstanding it is much slower in its effects than some of the others adopted in practice. This may arise from the fact, that the combination of the gelatinous tissue of the skin with the tannin is slowly going on from the immersion in the first vat of the series, at the same time that the lime is being removed, and, consequently, that the finished leather is more compact, and tougher, than if the swelling were made with acids in a shorter time.

THE TANNING.—The many improvements in reference to the combination of tannin with the gelatinous tissue of the skin, that have been put in practice within the last fifty years, seem almost to exhaust the subject. Hydrostatical pressure, the laws of exosmosis and endosmosis, exhaustion, or the vacuum principle, combined with mechanical action, have been successively tried, and the result is, that the time required for the operation, which formerly extended over two years, and sometimes longer, is now diminished in some cases to as many weeks. Unfortunately, it appears that, as the period occupied in the tanning is diminished, so also is the quality of the leather deteriorated, for although by the modern accelerated processes, a large amount of tanning agent is rapidly taken up by the skin, its union with the gelatinous matter is far from being complete, and the pressure or exhaustion applied to bring about

the rapid combination has the bad effect of leaving the leather porous, and without compactness or body. Hence, when a good article is required, such as shall combine density with closeness of grain and thorough homogeneous tanning, that which has been manufactured in a manner somewhat resembling the old system is still preferred.

This system consisted in spreading a layer of waste tan in the bottom of the pit, and over it another of fresh tan to the depth of an inch; upon the latter the hides was spread out evenly, and over it another stratum of tan. This alternate arrangement of tan and hides was continued till the pit was filled, when another layer of tan, six inches thick, was placed upon the whole, and well-trodden to compress the mass; the final covering was termed the *hat*. After a period of four months, when the bark was considered to be exhausted of its tannin, the contents of the pit were removed, the partially-tanned hides stretched, and again replaced with a supply of fresh tan in the same order as before, left for another interval of several months, then taken out, again stretched, and so on till they were deemed sufficiently tanned; the bloom being ultimately given with a concentrated extract of the bark. No moisture was allowed to enter the pit, except what was retained and absorbed hygroscopically by the bark; and as the tanning agent can come in contact with the skin only in a state of solution, it is evident that in the absence of sufficient liquid to bring it to this state, the method must have been slow and tedious.

Subsequently the plan was adopted of filling the pit with tepid water, the hides and bark being arranged as above stated, and new materials substituted for those exhausted every three or four months, till the tanning was nearly completed, the finish being given with a strong solution of tan liquor. Even by this course, which was a great improvement on the former, the hides took a period of eighteen months and longer to convert them into good leather. Another innovation followed; it consisted in filling the pit with tan-liquor or infusion of the bark, instead of water, the hides and bark being disposed as formerly. This mode is still much followed by Irish tanners, but is now deemed obsolete by most of the leather manufacturers of this and other countries. Leather can, however, be made by this method, unsurpassed by any other in quality.

It is rarely that ground tan is now used, the time of tanning being reduced, and leather of average excellence obtained by employing a solution or extract, termed *ooze*, instead. In the slow process of working, very little difference exists between the course followed by the various tanners; and where a difference is found, it is more in the manner of making the *ooze*, than in the succeeding manipulations. The adoption of solutions of tan has been gaining ground regularly from the time of SEGUIN, who first recommended it, and there is no doubt that it is much more effectual, as evidenced by the abridgement of the tanning period, than even the most finely powdered bark. There are several methods of preparing the *ooze*; cold water being employed by some; hot by others; while many extract the strength of the material by boiling; and, latterly,

the spent or weak liquor from the pits has been resorted to for this purpose. When cold water is preferred, the better way is to have a gallery of vats, in which the ground tan is exposed to the solvent action of the water. That which receives the water direct from the reservoir contains the almost exhausted tan, and, consequently, as the liquid passes from one vat to another, it meets with a richer material, and takes up more and more tannin, until, as it passes off from the last filled with the fresh bark, it possesses a high degree of concentration.

The same plan may be followed when hot water is used, in which case branch steam-pipes are laid to each vat for the purpose of heating its contents. By this means the extract is obtained of any degree of concentration, according to the quantity of water employed, and the time of digestion allowed. Sumach, divi-divi, and valonia, may be exhausted in the same way; but kino, and the several varieties of catechu, should be macerated by repeated agitation in the water. Divi-divi extracts should be made as much as possible in close vessels out of contact with air; and the tanning, also, when this substance is used, ought to be performed with as little exposure as possible, with the view of preventing the coloration of the leather.

Latterly, hydrostatic pressure has been resorted to for abstracting the virtues from barks and similar substances. A well-bound vessel is taken, and a perforated false-bottom inserted a short distance above the real one, and from the space between the two, an outlet pipe draws off the contents. It must be fitted with a strong and water-tight cover, supplied with two trap-doors, through which the bark may be inserted and removed, but capable of being perfectly secured. When filled with the bark, water is introduced through a pipe, which may be twenty or thirty feet high. By keeping the latter always filled, considerable pressure is exerted upon the contents of the tub, and by this means the tannin is more readily dissolved. The liquor is drawn off from time to time through a pipe, according as it filters through the mass.

Whatever be the means adopted for making the ooze, the next operation is the immersion of the skins in it, in order to convert them into leather. This is done by filling a number of pits sunk in the floor of the tan-yard, and introducing into them the swelled or partly-raised skins, beginning with those pits which contain a weak infusion, and after proper intervals, passing the skins forward into those which contain stronger solutions. In the construction of these pits, the practice is to excavate the earth to the depth of nine or ten feet, and to cover the bottom with a bed of retentive clay. The pipes for conveying the ooze, waste, tan liquor, *et cetera*, are then laid, and the intermediate spaces filled in with well-compressed clay. Instead of boards, bricks are sometimes used, and the inner surface is well secured with hydraulic cement. A composition of asphalte, made of the usual components, only substituting clay for chalk, would answer the purpose admirably. Such pits as contain the weak infusion of the tanning agents are called *handlers*, and those employed for finishing the process, and, therefore, having a stronger liquor, are known as *layers* or *bloomers*. In the weak handlers, the hides are taken

out twice a day, placed double one over another in a heap, and again introduced into the same or the next pit. After their removal to stronger pits, the handling, as the operation is called, is performed only once a day, and after they arrive at the layer-pits, they are taken out only once in the week, and finally once a month. The object of these handlings is to equalize and quicken the combination of the tannin with the skin; for during the time that the hides lie upon one another on the ledge over the pit, their weight forces the absorbed liquid out of their pores, so that they are more free to imbibe the juice on their re-introduction to it than before. Some are of opinion, however, that during the one or two hours they remain exposed, they contract some injury, and that the quality of the leather is much improved by transferring them at once into other pits; but, as will appear further on, a directly opposite view is often held. It is a common practice with many to introduce some powdered tan into the last pits or bloomers, between the hides, more especially when it is desired to produce a superior leather in point of quality and color. On the other hand, several manufacturers continue to use the powdered tan with the ooze throughout. To avoid the repeated handling of the hides, and the alleged injury from exposure, some tanners submit the hides to the tan-liquor in a vertical instead of a horizontal position. This method has the advantage of exposing every part of the skin to contact with the juice; but if care be not taken to alter the position at proper intervals, the lower part is liable to be better tanned than the upper, owing to the bottom of the pit containing the richer ooze. This, however, is very easily obviated by reversing the hides. Patents upon this principle were taken by Mr. KEASLEY in 1845, and by Mr. BARRETT in 1850.

The quantity of tan required varies with the weight and quality of the hides. Generally, heavy hides take about double their weight of good oak bark to tan them; but those which are lighter and of less body are perfectly tanned with a less quantity, from 1.6 to 1.8 of their weight. When sumac, valonia, divi-divi, or catechu is the tanning agent, a much less proportion suffices, since these materials, as already stated, are greatly richer in tannin than oak bark. With oak tan, the period required for tanning good sole leather averages ten months; about eight months when valonia is used; and six if *terra japonica* or catechu be employed.

The method of tanning introduced by M. OGÉREAU of Paris, is similar to the old system still followed in many parts of Ireland and Scotland, namely, the stratification of the pit with alternate layers of tan and hide; only that, in the French method, the pit is furnished with a false or hurdle bottom, through which the liquor in the vat filters, and collects in the space below. Once a day or oftener, as the case may be, the filtered juice is raised by a pump to the top of the vat, from which it gradually descends through the materials, to be again successively raised to the surface. By this means the tan juice in the pit is kept in circulation, and brought into close contact with the hides. At the end of a month the contents become exhausted, and fresh materials are introduced, the circulation being kept up as before. It is said that by this method the time occupied

in the tanning does not extend beyond four months, and that the leather is of first quality.

NOSSETER, in 1844, patented a method by which the pressure of the overlaying hides in the pit, which prevents free contact with the tanning liquor, is counteracted, and the conversion of the hides into leather much accelerated. This method consists in constructing within the tan-pit a frame with ledges, which support other frames on which the skins are placed when introduced into the pit. Even when fixed as closely as possible together, as many skins cannot be introduced as in the old way; but taking into consideration the limited time in which the operations are finished, the patentee states that, in the end, a larger number can be tanned by this method within a given time than by the ordinary arrangement. After all the frames and hides are placed, the pit is filled with ooze, and after it has become exhausted, the spent liquor is pumped out and fresh supplied, and this is repeated till the leather is formed. Another improvement embraced in this patent consists in depriving the hides of the old tan-liquor previous to immersing them in the new, by submitting them in numbers at a time to the action of a screw-press, so constructed that the hides do not require to be folded, but are laid flat on the table or press-board.

The plan adopted by BERENGER and STERLINGUE for tanning hides in a reasonably short time, without the aid of machinery, is the following:—A row of pits is formed, each furnished with a hollow vertical wooden cylinder, connected with the next pit of the series by a pipe fixed at a depth of six inches from the surface, and communicating with the space between the perforated and true bottom, by means of a punctured pipe. By this arrangement, the liquid in each pit may be made to pass over to the next in the series, and so to the end, without the least disturbance of the contents. Thus, if water from the supply pipe be conveyed into the first vertical cylinder in the series, the liquid flows down through the false bottom into the intervening space, causing the fluid already there to ascend through the body of the vat, and to flow over by the connecting pipe into the cylinder of No. 2 pit, where it displaces an equal volume of liquor in like manner. In working on this principle, a series of eight pits is preferred; No. 1 is filled with tan and hides in the old manner, and as much water as it will retain added. After twenty-one days, No. 2 is filled in the same way; but instead of employing water, as much strong ooze as is required to wet the materials is poured into the first pit, and this drives before it the weak liquor, which ascending by the pipe from the false bottom into the cylinder, flows over by the connecting pipe into, and moistens the contents of, No. 2, with the weak tan liquor of the first pit. After the lapse of another period, a third is charged with tan and skins, and after this a quantity of strong ooze, equal in bulk to what is necessary to moisten the contents of the new materials like the others, is poured into No. 1, when the liquor previously contained in it will flow over from the cylinder to No. 2, the liquid contents of which are in like manner transferred to No. 3. In this way the work progresses till the eight pits are filled. The connecting pipe of No. 1 is then closed, and the ooze in it pumped out, and the remaining

materials removed, when the leather will be found thoroughly tanned. A fresh supply of hides and tan are then put into this pit, which now becomes the last or eighth of the series, that which before was No. 2 becoming No. 1, and receiving the strong ooze. By this means the hides are tanned without once removing them from the pits till they are finished, and likewise with a great saving of labor. If the strong infusion be added at intervals of fifteen days, the time required does not extend beyond four months, but it may be prolonged at will, by allowing a period of twenty or thirty days to elapse between the addition of fresh ooze, or the filling of a new pit. The ooze used in the foregoing operation is prepared in a series of vats similarly constructed, or they may be placed one above another, so that the liquid in the higher may flow into the next beneath, as in the lixiviation of soda or of kelp—see IODINE—only that each is furnished with a coil of steam-piping, for the purpose of heating and concentrating the liquors, with a view to the removal of gallic acid and other substances. The liquor emptied from the tan vat is mixed with the ground bark or other material in the first of these, and after a while, the solution is drawn off to the lower one, where it becomes further enriched. In this way the liquid may be brought to any degree of density necessary for the operation, and much of the extractive and gallic acid may be removed.

Another patent process by CAGSWELL, recommends the process of filtration, as a means of causing the tannin of the ooze to unite with the matter of the hide in a shorter time than is ordinarily required. The prepared hides are to be laid in sawdust, in such a way as to form a kind of basin, and into this the rich ooze is poured. Gradually it finds a passage through the cells of the skin, and passing out at the other side, runs through the sawdust into a tank beneath or adjacent to the floor, but whilst going through the hide, the tannin is retained. By keeping the hollow of the hide filled with fresh ooze, the gelatino-fibrous tissue in a very short time becomes saturated with tan. There are some drawbacks, however, to this method; for instance, the porosity of the hide is very unequal, and as the filtration is greater where most porous, these parts are liable to be overtanned, when the others may not be sufficiently so. Again, the edges are never finished in this operation, and consequently, the hides, after the body has been made into leather, must be subjected to ooze in the pit. The great space, too, necessary to carry on an extensive trade by this means, is not among the least objections to it.

Besides the preceding methods in which the tanning agent is left free to react upon the skins, several others have been patented in which mechanical force, in concert with other means, has been employed to effect the tanning in a shorter time. The simplest of these are such as merely cause the agitation of the hides and tan-liquor in the vat, so as to effect a more thorough and rapid contact of the combining substances. Of several on this principle, that of Mr. SQUIRE of Warrington, patented in 1845, will be sufficient to illustrate the method pursued. A cylindrical drum or barrel is divided internally into four compartments by bars, space being left for the liquid of one part to flow into

the next as required. The hides are introduced into these divisions by doors which are well secured, and the tan-liquor, which may be that of divi-divi, catechu, or any other, in quantity sufficient to fill the cylinder to more than three-fourths. All the openings are then perfectly secured, and motion is given to the apparatus by means of a winch fixed upon its axis, or a strap passing over a drum, and connected with the engine shaft. The rotation is slow, but sufficient to keep the hides and fluid contents in motion. In the course of a very short time the hides are well tanned by this method, and the air being excluded during almost the whole period, the leather retains a good appearance, even when divi-divi and catechu are the agents employed.

Some erect a roller over the mouth of the pit, and string the hides together by stitching in the form of an endless web or belt, which is wound in several coils loosely round the roller, and then placed so as to be partly submerged in the ooze of the pit. By turning the cylinder, the immersed portion becomes saturated with the liquid; and as it rises again on the roller, the weight of the suspended hides exercises a force by which considerable quantities of the liquor are squeezed out, and the hides descend at the other side in a condition to absorb fresh liquor. This alternate absorption and expression of the liquor is very conducive to rapid tanning; but the time is still further abridged by a process patented in 1837 by COX and HERAPATH, which consists in passing the hides between two rollers fixed longitudinally over the pit. In order to avoid injury to the hides from contact with the metallic surface of the rollers, and to allow the solution to pass away more readily, the lower cylinder is covered with horse-hair cloth, and the upper one with folds of flannel. Both rollers revolve, and the upper one may be weighted to any degree, so that the hides passing between them lose all absorbed water and re-enter the same pit, or another containing a stronger ooze, in a condition to imbibe the solution very readily. It is stated that sole leather may be thoroughly tanned by this method in one to two months, and kips for upper leather in three or four weeks. It should be remarked, however, that although with care an average quality of leather may be prepared in this manner, yet, if too much pressure be exerted, the process of tanning will be rather retarded than otherwise, because the elasticity of the tissue will be destroyed.

Tanning by Hydrostatic Pressure.—SPILSBURY, in 1831, was the first to introduce the method of permeating the hides by hydrostatic pressure. His mode consists in securing any holes or damaged parts in the hide, and then to stretch it on a suitable frame, having iron hooks for fastening the edges of the skin all round. Upon the frame so furnished another is laid, and screwed tightly, so as to allow no room even for water to percolate between the two frames. Another hide is then fixed upon the second frame, and its edges secured in the same manner by a third frame, the whole three being bolted firmly together by means of clamps. In this way a kind of water-tight compartment is formed between the two hides. The frames are then placed upright, and the interval between the

hides is filled with ooze. As the skins form the side walls, it is evident that their whole surface will be exposed simultaneously to the liquor, and as the latter by the force of its own weight penetrates them, the tannin enters into combination, and they are gradually converted into leather. An arrangement of pipes and stopcocks permits the confined air to escape in the first instance, and afterwards the spent liquor, after it has percolated through the hides. Of course the rapidity of the tanning by this, as by other processes, depends more or less upon the thickness of the hides, the strength of the ooze, and the amount of pressure exerted.

DRAKE, instead of using frames, directs that the hides should first be submitted to an incipient tanning, and then sewed together in pairs, so as to form a kind of sack. A small aperture is left at the shoulder or neck part for the introduction of a funnel for filling the sewed hide with the tanning juice; and to prevent the distension to which the hides would be liable on being filled, he places each pair in an upright frame of suitable size. The bag being filled with the ooze, the liquid percolates through the pores of the skins, being deprived of the tannin in its passage, and trickles down into a receptacle beneath the frame, whence, if rich in tannin, it is pumped back into the bag in order to be again exuded. Towards the close of the operation, when the skins become firm and hard, so that the confined fluid exudes very slowly, the atmosphere of the room is heated to about 150°, with the view of promoting the permeation of the ooze, and the process is continued till the hides give indications of being thoroughly saturated with tannic acid, which is known by their beginning to darken in places, and by the passing through of the ooze without losing strength. The contents of the bag are then withdrawn, the stitchings cut open, and the leather subjected to the finishing processes, which will be presently described.

By the improved methods of CHAPLIN and COX, the hides are sewed up into bags, leaving a small aperture for the introduction of a branch pipe from the main, connecting them with a tank which holds *hot ooze*. On turning a tap, the ooze flows into the bags by means of the branch pipes; and provided the connection and sewing be secure, the pressure exerted may be varied at pleasure, according to the height and quantity of liquor in the vat. As the hides are necessarily extended more or less under the force so exerted, frames answering to the size of the bags are used to keep them from bursting or being too much expanded. The plan of encasing the sewed hides in canvas or flannel, has been patented as an improvement on the practice of placing them in frames or boxes of wood.

PEACHY, POOLE, and others employ force pumps and other similar means to cause the tan-liquor to penetrate the hide, but the principle of hydrostatic pressure is still retained.

All these methods by infiltration are subject to the disadvantage arising from the unequal permeability of the hides at different parts, and from the weakening of their structure consequent on the prolonged distension.

By Exhaustion of Air.—KNOWLIS and DUESBURY, to avoid the evils which hydrostatic pressure occasioned, had recourse to infiltration produced by the

exhaustion or rarefaction of the air in the vat, in order to tan the hides more regularly. For this purpose the hides are suspended within an air-tight vessel from cross beams furnished with hooks. To economise room, they are arranged as closely as possible without touching, and weighted beneath to keep them extended. The top of the vessel is movable, and the pipes for exhausting the air by the pump, or for forcing air into the apparatus, are fixed at the sides near the top. When ooze has been introduced till the hides are covered, and the lid is firmly screwed down, the air is exhausted, and the contents left to their natural reactions for twenty-four hours or more. The air is then admitted, and the ooze drawn off. During three hours the hides are now left in the vessel in contact with the air, till in fact they become saturated with it, and when this period has elapsed, the tan liquid is again introduced, and the exhaustion renewed. In this way, the alternate filling of the vat with liquor, exhaustion, and exposure to air, are continued till the leather is fully formed, taking the precaution to employ stronger ooze as the operation proceeds.

By endosmosis.—The process patented by TURNBULL in 1845 embraces a combination of the exosmotic and endosmotic principles. The hides, sewed into bags, are filled with the ground tanning material and water, or a weak ooze, and the bags are then immersed in a vat filled with a strong extract of catechu, freed as much as possible from catechuic acid by solution in cold water and filtration. The inequality of density between the weaker liquid within the bags, and the stronger solution contained in the vats, causes a motion by which the exterior penetrates, and the interior solution exudes, both parting with tannin to the gelatino-fibrous tissue, and causing its saturation in a very short time without the intervention of any mechanical force. To expedite the operation, the liquid in the vats is rendered denser by dissolving in it salts or sugar in the proportion of fourteen pounds to one hundred gallons. During the tanning, it is necessary to keep the bags filled by occasional additions of water or weak ooze, and likewise to maintain the density of the liquor in which they are immersed, as this causes the endosmosis or infiltration, and consequently the exosmosis or exudation, to be more rapid.

By acupuncture.—SCHNYDER, some few years ago, obtained a patent for a quick process of tanning, effected by exposing a more extended surface of hide to the tan-liquor than is ordinarily done. His method is to puncture the hides with steel points either by hand or machinery, with an instrument having from one to three hundred points to the square inch, and afterwards to expose the skins so indented to the action of the tan-juice, with or without pressure, as may be most convenient. Either the flesh or hair side may be operated upon with the steel points; and, notwithstanding that such perforations permit the liquor to enter into the interior portions of the skin, still, as the tanning approaches completion, they close up, and the leather is as capable of resisting moisture as that made from hides which have not been subjected to the same operation.

According to MORFIT, this method is more worthy

of attention than most others, owing to the combination being so readily effected between the skin and tan that the ooze has not time to acidify before it becomes exhausted, and so the relaxation and expansion of the fibres, the enlargement of the grain, and consequent brittleness of the leather which acids produce, are obviated. Also, because by this method the formation of leather takes place in the heart of the hide as readily as at the surface, the overtanning of the latter, by which it becomes rigid and brittle under the old system of prolonged exposure in the tan vat, is done away with.

Mineral Tanning.—It has been shown in the introductory portion of this article that gelatin, fibrin, and albumen, are capable of combining with and precipitating metallic oxides and basic salts from their solutions. On this reaction have been founded certain processes for converting skins into what may be called a *mineral leather*, by impregnating them with suitable metallic bases. This is easily effected by merely placing the raised and depilated hide in contact with solutions of such bases, when the affinity of the gelatino-fibrous tissue for the mineral compounds results in their combination. Alum has long been known as a compound capable of rendering light skins imputrescible—in fact, of converting them into leather; but this agent has not been used for making ox or such hides into sole or upper leather till lately. The first to draw attention to the manufacture of leather suitable for all ordinary purposes, without the aid of tannin—considered as a branch of trade—were D'ARCET and ASHTON; but their attempts, although they suggested the idea, left very much to their successors to accomplish.

BORDIER, in 1842, obtained a patent for an improvement in this department, which deserves more attention than the methods of his predecessors. On this system the hides are to be washed, depilated, and raised by any effectual method, and then exposed to the mineral constituent, which consists of a subsulphate of sesquioxide of iron, prepared by digesting twenty-two pounds of protosulphate of iron—copperas—in a mixture of two parts and a quarter of nitric acid, specific gravity 1.33, and three pounds one ounce of sulphuric acid, of 1.848 density. A stone-ware jar may be employed for this purpose, the contents to be heated with steam, and stirred repeatedly. As soon as the red fumes of peroxide of nitrogen— NO_2 —cease to be evolved, the vessel is to be removed from the heat, and the mixture kept agitated, till, as it cools, it forms a kind of paste. After settling for twenty-four hours, it is to be diluted with water, and some further portion of sesquioxide of iron added. It is again left for several days, with occasional stirring, for the purpose of allowing the sulphuric acid to take up the sesquioxide of iron and retain it in solution. The cleaned skins are then immersed in the bath, and stirred about or handled occasionally, as when working in the tan-pit, till they are made into leather. With light skins this happens in three days or thereabouts, and in six to eight days with thick skins intended for sole leather. During this immersion a combination of a basic salt—a subsulphate of the sesquioxide of iron—takes place, and an acid

salt with uncombined sesquioxide remains in the bath. There is little doubt that the acid liberated in consequence of the union of the base with the skin must have an injurious effect upon the leather, as is the case when tan is used; and if this be so, a method of working in which the uncombined acid might be neutralized as soon as disengaged from the iron base, would be preferable.

CAVALIN's mode is to impregnate the cleansed, depilated, and partially-drained hides, with a solution made of ten pounds of bichromate of potassa and twenty of alum, in one hundred and eighty pounds of water. For this end they are immersed during four days, being handled once in the twenty-four hours, and rubbed, if necessary. Much of the success of the finishing process depends on the thorough manner in which this first saturation is performed, and therefore the strength or density of the bath is kept up by the addition of more of the above salts, in proportion as the hides absorb what has been already dissolved. For the second step in the process, the vat is filled with a solution of copperas—protosulphate of iron—using one pound of this salt for every gallon of water. The hides saturated with the aluminochromic solution are immersed in this bath in such a way as not to touch one another, nor the walls of the vat. At an interval of twelve hours they are drawn out, allowed to drain for a short time, and again plunged into the bath; the alternate draining and immersion being thus continued till the leather is formed. It is necessary to maintain the strength of the bath, as the iron enters into combination, by adding more of the salt. In this operation the iron base is peroxidised in the hide by means of the chromic acid, which is itself reduced to the state of sesquioxide, and remains, with the iron and a portion of the alumina base, firmly united with the tissue. The time extends over from five to six days for upper leather, eight or ten for Swedish sole leather, and thirteen to nineteen for thick *butts*. After the finishing of the operation, the hides are drained, and then thoroughly soaked in water to remove everything that has not entered into combination. Upper leather prepared by this method is said to be soft and pliant; and the thick sole leather is alleged to have a body and imperviousness that render it equal for wear to the best tanned leather. The same inventor recommends another method of making leather of skins, by first submitting them to a dyeing process, employing a strong dye beck, in which four ounces of alum are added to the gallon of liquor. Frequent immersion in this solution reduced to the proper strength—as determined by a preliminary test with a bit of prepared skin—is necessary, till the materials assume a light-green yellow color on the grain, and yellow-green on the flesh side; after this they are drained and finished in a bath made by dissolving ten pounds of bichromate of potassa in eighteen gallons of water.

FINISHING PROCESSES.—Such are the principal methods followed in the tanning of hides, but after this operation has been performed, the hides are not in a fit condition for the market; they have still to be submitted to several additional processes. When

thoroughly tanned, the hides are taken out of the layers or bloomers, and washed slightly, or brushed with water to remove all extraneous matters, without, however, detaching the bloom which is so much prized, and is regarded as a kind of guarantee for the quality of the leather. They are then hung up to dry in a spacious and well-ventilated apartment, from which the sun's rays are excluded. Much care is necessary in the drying: if conducted too rapidly, the hide is liable to crack on the grain side, owing to the rapid and unequal contraction of the inner and outer parts; on the other hand, it must not be so slow as to allow the leather to get mouldy. In winter, a medium temperature is maintained in the drying-room, or loft, by means of steam-pipes, judiciously placed so as to give out their caloric to the air of the place. When partially dried, the leather intended for soles and other similar uses where great impermeability is required, is submitted to a process for condensing it, and destroying in a great measure the porosity which it retains after the tanning has been executed. Formerly, this was done by hammering the leather on a smooth table with heavy mallets or hammers, almost in the same way as the shoemaker hammers his leather upon the lapstone; but subsequently machinery was substituted. In many concerns, the compression is effected by means of rollers of brass surmounted by a carriage, loaded with ten to thirteen hundredweight.

STERLINGUE was the first to introduce a hammer moved by machinery for condensing the leather, but in his invention numerous requisites were found wanting, so that it was often necessary to finish the leather by hand with the hammer or mallet. In 1840, DEBERGUE patented another apparatus, in which a roller attached to a weighted lever, with other regulating mechanism, was the compressing agent. The hide or side of leather being placed upon a strong table faced with brass, and having either a plane or concave surface, was submitted to the action of the roller. COX and WILTSE have lately introduced machines which are analogous in their action to the preceding, but are simpler in their construction. Another machine was introduced by M.M. IRAN and SCellos in 1852, of which report speaks favorably; but as the object of all these machines, of which there is a great variety, is simply uniform compression, either by beating or rolling; and as the details of their construction would too much extend this article, the Editor forbears to enlarge upon a subject purely mechanical.

After the rolling or hammering, as the case may be, the sides of leather are hung up again to dry, and left with occasional changes of position, till all the moisture is removed as far as possible. After this, the sides are in some instances stored by laying them one above another, and weighted; their position being changed from time to time before they are sent to the market. This storage is supposed by many to improve the quality and color of the leather, but others regard it as unnecessary trouble.

CURRYING.—Such are the processes through which heavy or sole leather passes. With upper leather, or that prepared from lighter skins, a different course is pursued—the rolling or hammering being dispensed

with, and another set of operations termed *currying* being practised. In some cases, the finishing of the leather to suit the shoemaker, coach, and harness manufacturer, becomes a distinct and independent branch of business from that of the tanner; but in many establishments, the two are carried on together, so that the finished leather issues from the tannery.

To curry leather, so as to confer qualities which adapt it for the boot and shoe maker, the carriage and harness maker, and other particular applications, requires its subjection to various processes, which, independently of the tanning, according as they are well or imperfectly accomplished, affect in a great measure the suitability and lasting qualities of the leather. From the difference of treatment which becomes necessary to confer these qualities, result the numerous designations by which the finished material is known. Thus, a distinction is made between smooth or sleek leather, tallowed, oiled, and waxed leather, with several other varieties. In the variety and quality of their curried leather, the manufacturers of Great Britain are far behind their French brethren. The heavy upper and harness leather produced by the British currier cannot be excelled; but when a light article is required for summer wear, and which should retain its suppleness, the inferiority of the British leather, compared to the French, becomes apparent to the wearer after a very short time.

The role of operations required for this finishing may be enumerated—the dipping or soaking, the beating, stretching, oiling, tallowing, waxing, dyeing, and polishing.

Soaking and Beating.—As the tanned hides or skins come from the tanner they are dry and hard, but before they can be submitted to any of the finishing operations of the currier, they must be rendered soft and pliable. This is done by soaking them in water, or sprinkling them with that liquid, and allowing them to rest till they become sufficiently moist. When this happens, the side is placed upon a rectangular hurdle of basket-work, and trodden with the feet—the operator wearing heavy wide shoes for the purpose—or else beaten with an instrument called a *mace*. The working is continued carefully so as not to tear or injure the leather, till it becomes sufficiently soft and pliant, and when this is effected, it is placed upon the horse, and worked with the *cleaner*. There are various kinds of this tool, but, in all cases, the sharp edge of the instrument is so formed as to prevent it entering too far into the leather. By its use, the inequalities and overtanned parts on the flesh side are shaved off, and an uniformity of thickness and regularity of surface produced.

Stretching.—By the preceding treatment, the grain of the leather is brought out, but the desired equality is not attained till after it has undergone the *stretching* and *pommeling*. The former is executed by means of tools of steel, copper, or brass, or of hard stone or glass, the latter materials being resorted to when a better and smoother surface is desired. After the shaving on the horse or beam with the knife, the skin is further soaked in cold water and scoured, then placed with the flesh side under upon a smooth stone

or mahogany; and the workman, grasping the wooden handle of the stretcher in both hands, holds the tool almost perpendicular to the side of leather, and forcibly scrapes the surface, especially where there appears to be inequalities. By continuing this action, usually from the tail to the head part, over the entire surface, and using water freely in sprinkling, the whole is brought to an equal thickness at the same time that it is stretched, and the *bloom* of the leather more developed; density and smoothness are also acquired.

Pommeling.—The partially prepared hide is now submitted to the last operation called *pommeling* or boarding. The pommel is of hard wood, having a smooth and fluted or channeled side, the former being next the hand, and the latter for acting on the leather. Fig. 351 shows this instrument with the strop intended to confine the hand of the workman, so as to give him greater power for applying it. According to the fineness of grain required, so do the grooves in the pommeler or crippling board become finer and sharper.

Fig. 351.

Usually the grooved side of this instrument forms an arc of a circle, and the surface next the hand being straight, forms as it were the chord of that arc. This construction allows of considerable body in the middle part, whilst at the extremities it is thin. In using it the workman doubles the hide with the grain side in contact, and strongly rubs it on the flesh side, applying the force outwards, and then reversing it. This mode of working is ordinarily termed the *graining*, to distinguish it from the *bruising*, which takes place when the operation is performed on the grain side of the leather. In many instances the hides are again damped, and worked under the *slicker* or *stretcher*, and then dried and placed one upon another, and weighted for some time in order to complete the process; or they may be whitened by rubbing the flesh side with a sharp knife on the horse, after the action of the *grainer*, in which state, provided the leather be treated with oil or tallow before the last workings, it is known as *finished russet*. Leather prepared in this fashion is called *stretched leather*, but it may be made into *sleek* or *grain leather* by a few further operations, and a very slight modification of those described.

Grained Leather.—To render the hides—which are in most cases cut in two and pared—pliant and even in body, they are drawn over a flame from straw or such material, the flesh side being that so exposed. Fatty matters, which vary with the choice of the currier, though tallow or mutton suet is preferred, dissolved if required by heat, are then laid on the flesh side in a coating, by means of a brush or mop, to the extent of three to four and a half pounds for cow hides, and one for thick calf skins. After this *dubbing*, as it is called, the hides or skins are doubled up, the hair side being inwards, and remain so for some hours, or in some instances one or two days; they are then refolded, and put into a tub containing water, where they soak for eight or ten hours, being worked during this time

more or less, so as to detach the fatty matter on the surface of the leather. When the whole of the pieces assume a uniformly white appearance, they are taken from the soak, and beaten with a *mace*, afterwards worked by the pommel till the grain is brought out, then cleaned with the sharp knife on the horse or beam, and finally, any creases removed by working and polishing them with the brass and glass slicker. This being done, the leather is slightly sprinkled with water, and, if necessary, cleaned and then hung up to dry. When it is required to color the product, the latter operation is not carried too far, so as not to necessitate its moistening again. The operator now rubs on the hair side, by means of a brush, a solution consisting of a sesquiacetate of iron, prepared by digesting scrap-iron in sour lies or beer, or of logwood, nut-galls, gum, and copperas.

Several coatings with such a composition are applied, the leather being partially dried after each, folded up, and worked under the stretching and polishing iron in order to give the finish. Before being sent out, however, it is rubbed over once or oftener on the grain side with a piece of woollen stuff dipped in sour beer or barberry juice, worked by the pommel and slicker, and finally, exsiccated. This kind of leather is much used by the saddler, trunk, harness, and coach makers. Of course, very many modifications in the order of application and execution of the foregoing treatment of the hides are practised by different parties, but the preceding general view of the operations will indicate the nature of the business.

Oil Leather.—Calf and cow leathers are curried in oil very extensively. The preliminary dipping, treading or working, *et cetera*, are applied, in order to give the substance more suppleness. Fish oil is recommended, but the French prefer the material usually employed for scouring skins that are intended for chamois leather, and which consists of fish oil and potassa. It is thicker than the ordinary oil, and becomes more rapidly absorbed; besides it gives greater pliancy and softness, and less is required than of the fish oil alone. Neat's-foot oil is likewise used, and it is said to add materially to the good qualities of the leather, but a proportion of fish oil must be mixed with it. When applying the dressing or oily matter, the skins should be slightly moist, so that, as they dry, the oleaginous portion may be gradually and thoroughly absorbed. Should they be too dry, the oil would be soaked too quickly, yet not properly combined so as to render it sufficiently resisting to water or moisture; on the other hand, excess of moisture must be guarded against, as in this instance too much oil would be expended, and the time would be prolonged in proportion. A coating of oil is uniformly spread over the grain and flesh sides, after which the hides are hung up to dry, the direct rays of the sun or too violent a draught being guarded against. In summer time the drying is effected in twelve hours, though in winter it sometimes requires three or four days. When dry, they are again full, and a further coating of fish oil mixed with the fatty scourings already mentioned, only in smaller quantity than in the previous case, laid on, and the process is repeated after the drying of the leather as before. Finally, the grain side is cleaned by rubbing it well

with a brush and a weak potassa lie. The coloring of the grain or flesh side, as the case may be, follows these operations, and is effected by employing the dye already alluded to. After receiving one coat, the leather is pommeled crosswise; another layer of blacking applied; dried and pommeled, or stretched, according as it is deemed necessary; rubbed over with a cork pommel to give a smooth surface, and finished by giving a light coating of oil on the hair side.

Varnished Leather.—During the last few years a considerable quantity of a light glazed or varnished leather, intended for the manufacture of patent boots and shoes, has been introduced into the market. The French are celebrated for the beauty and superior quality of their manufactured product. This kind of leather is simply tanned kips, calf-skins, or split ox-hides of superior quality, well curried, and then passed through two other operations—one intended to render the leather impermeable to the varnish, and the other the laying on of the varnish. In currying leather intended for this manufacture, it is necessary that the fatty or oleaginous matter be laid on as thinly and evenly as possible, in order to insure the uniformity of the article after being prepared.

Such curried skins are taken and rubbed over, either on the flesh or grain side, with a coating of boiled linseed oil mixed intimately with ochre, ground chalk, or some such substance, and dried; the coatings are renewed after each desiccation till it has received three, after which the surface is well rubbed over with a pumice-stone tool till it appears even, and the fatty and other matter is compressed into the pores of the leather. When this is done, other layers of a thinner material than the above, but of the same nature, are applied, and after drying, rubbed into the skin as before; by which means the adjacent part of the skin becomes thoroughly saturated with the fat, and an even surface is given to it. After this part of the work is executed, the prepared surface is coated over two or three times with a composition made with boiled linseed oil, but without mineral matters; subsequently adding lamp-black and as much turpentine as will make it flow freely. This is laid on evenly with a fine brush, and allowed to dry after each coat, till a sufficiently black and shining surface is given to it; for which purpose it is rubbed over with a piece of woollen stuff and the finest kind of pumice-powder or tripoli.

The leather is now ready to undergo the final operation or varnishing, which consists in laying on coats of a composition made of boiled linseed and copal varnish, with which any coloring matter intended to show on the leather is incorporated. Generally this is composed of twenty pounds of boiled linseed oil, such as is employed in the first operation, twenty of turpentine, ten of thick copal varnish, and one pound of asphalte, Prussian blue, or ivory black in the finest possible state of division. In making it, the oil and tinctorial matter in finest powder are incorporated, then the varnish is added, and finally the turpentine, the whole being so well stirred as to insure a homogeneous mixture. It is then set aside in a warm place for two or three weeks, after which it is ready for use. It is necessary that the utmost cleanliness in regard to the

manufacture be observed, and that no dust or other matters be allowed to float in the atmosphere, either of the apartment wherein the coatings are given, or in that of the drying chamber, as this would injure the smoothness and brilliancy of the article.

The number of varnish coatings applied varies, but five is the ordinary limit, the drying being effected after each in the chamber intended for the purpose, the temperature of which is kept at 160° and under. In this way a brilliant surface is given, and the leather has the property of resisting strains and of bending without the least crack or any injury to the even and perfect surface of the varnish.

It has been stated that the black varnish generally used for boot and shoe leather, is colored with lamp-black and Prussian blue, but the tint may be varied; thus for blue leather, Prussian blue or ultramarine mixed with a little Krem's white, and incorporated with the varnishes, answers well; lakes are used to give a red color; white lead for white; ochres for yellow, and so on, the shade being varied at will. An inferior quality of polished leather is made for belts and coach harness, by impregnating the skins with the linseed oil varnish, mixed at once with the lampblack and Prussian blue, copal varnish and turpentine. The linseed oil varnish is made by boiling, say, five gallons of this material with four pounds and a quarter of white lead and an equal weight of litharge, till the compound acquires the thickness of a dense sirup. For particular uses this is mixed with ochre, powdered chalk, or ground bones, as in the first operation for making a superior dress-boot leather.

NOSSITER of Birmingham obtained a patent for making sheep and goat skin leather into this article. He splits it by machinery and, on the new surface produced by the section, forms a grain by polishing with a slicker, and then lays on the varnish. It is said that by this means a better surface is obtained than when the outside, either on the hair or flesh side, is operated upon.

Split Leather.—With reference to the preceding patent it may be here stated, that a considerable number of hides are now split by machinery, generally after receiving a slight tanning, and the divided parts afterwards fully tanned and curried, so as to adapt them for the manufacture of light boots, shoes, and other applications. It is almost unnecessary to remark, that leather which has been subjected to this operation, is much weaker than that which is manufactured in the entire state. A large proportion of cheap and inferior articles are formed of split leathers. Ox hides, kips, and skins, so split and tanned, are chiefly used by shoe and boot makers for the inner soles, by trunk and portmanteau makers, and in carriage facturing; whilst the sheep and goat skins, similarly treated, are converted into the finer kinds of glove leather.

FANCY LEATHERS.—Besides the various kinds of leather already described, there are many others, included under the name of *fancy* leathers, which are extensively used, and are therefore manufactured on a large scale. Such are the well-known Russian leather, *morocco*, Hungarian, and chamois leathers, with a few others of lesser importance, but which, nevertheless, merit a short description.

Russian Leather.—This article, known as *juten*, has long been valued for its qualities of resisting moisture and the ravages of insects, as well as by the peculiar odor it possesses—qualities which render it of great importance to book-binders and others. RUSSIA was long the only country that produced it, but it has lately been manufactured in Paris. Its odor and particular qualities are attributed to the essential oil of birch bark, with which it is impregnated after the tanning with this material. In Russia it is manufactured from all kinds of skins, but in Paris, and wherever else the product is imitated, only sheep and goat skins are operated upon.

The method of preparing this article, is not very generally known out of the seats of the manufacture, but the following details from the memoir of COUNT DE KARTSOFF on the subject will give an insight into the process:—The dried skins are softened by soaking in water for five or six days in summer, and ten or twelve in winter; well cleaned and deprived of their hair by the use of milk-of-lime, prepared by disseminating one hundred and eighty-five pounds in a vat or tub eight feet in diameter, and seven feet three inches deep, nearly filled with water. During the steeping the skins are frequently examined, and as soon as the hair and epidermis are found to be detached, they are worked upon the beam with a dull knife, and afterwards with a sharper instrument, on the flesh side, to separate extraneous matter. When ox and cow hides are operated upon, the depilation is effected by piling them one upon another, sprinkling some common salt upon them to resist the injurious effects of over-fermentation, and after the proper time has been allowed, working on the beam as before. Bran-water baths are occasionally resorted to for the same purpose, but only when the more delicate skins are treated.

The usual steeping and beating, *et cetera*, are given after the depilation, with the view of removing the lime; and after this is done, the cleaned pelts are introduced into a vat like that described, containing a fermented menstruum of eleven hundred pounds of rye, and four hundred and fifty of oatmeal, six pounds of salt, and a sufficient quantity of leaven. They remain here for forty-eight hours or longer, according to circumstances, in which time they become *raised*. The tanning process is then commenced by steeping them for some time in a weak infusion of oak or willow bark by preference. After this the skins are placed in a tan-pit, interstratified with layers of coarse willow bark till it is full, and then charged with the liquor of the last steep, the whole being pressed by planks and stones. Fifteen to twenty-eight days are allowed to transpire before they are disturbed; at the end of this period the pit is emptied, fresh bark and solution substituted for the exhausted material, and the whole left as before. Three to six such changes and terms are required, according to thickness and weight of the skins, to finish the tanning; very thin skins get but two changes. Whilst tanning, the leather acquires rigidity, which is removed by immersion for a day or longer in a thin paste made of one hundred and thirty pounds of oatmeal, and nine or salt, macerated with warm water. This quantity should serve for one hundred and fifty skins of ordinary

size. When taken out of this steep, the leather is well cleaned, and allowed to drain. At this juncture the currying commences, which confers the particular virtues already mentioned. The leather still moist, but not over-saturated, is placed with the grain side downwards on a table, and crated with a mixture of oil obtained from *sea calves*, and that distilled from birch bark; the proportions are varied according to circumstances, but for the most part, one of birch oil to two parts of the other is the standard composition. This, in quantity of about nine ounces to each medium-sized skin, is laid on with the hand so carefully as to insure an even and entire coat. This done, the skins are stretched upon cords in an open shed, and left so till dried.

The Baskirs and Kirguises prepare their skins by smoking them, in lieu of tanning. The hair is detached by scraping them, while in the green state, with a broken sickle attached to a handle. When this is done, the skins are attached to cords placed parallel to one another in a pit, the depth and breadth of which depends upon the number of skins to be treated at once, and which is connected with another, at the distance of five feet, by a tunnel at the bottom. The pit containing the skins is well covered, and a fire of dry and decayed wood lighted in the other, which is likewise protected. As no immediate means of escape exists, the smoke passes over into the pit charged with the skins, by the tunnel or gutter at the bottom, and in the course of two or three weeks that they are exposed to its action, converts them into a leather which is said to possess a degree of impermeability superior to that of any tanned leather.

The method pursued in France for making Russian leather is as follows:—

The skins are deprived of hair by steeping in a lime vat, or in one containing a mixture of lime and potassa lie, but too weak to act upon the fibre, and scraping on the beam; they are then rinsed and fulled for a longer or shorter period, according to their body, and subsequently allowed to ferment in a steep, being first well washed in hot water. Eight days are allowed for this operation, at the end of which time they are taken out, again fulled and washed, and, if necessary, submitted a second time to the vat, in order to open all the pores. When this is properly done, they are taken out, well washed, placed on the beam, and worked with the flesher on both sides. After this a paste is made, sufficient for two hundred skins, of thirty-eight pounds of rye-flour. This is allowed to ferment, then diluted with a sufficient volume of water, and the skins are immersed in it during forty-eight hours; and at the end of this time they are transferred to smaller vats, and allowed to remain in them for fifteen days, when they are taken out and well washed in running water.

They are now fit for the tanning, which is done by putting them into vats filled with extract of willow bark—*salix cinerea* and *salix caprea*—of such a degree of heat as will not injure the animal fibre. Whilst in this solution—usually a week—the skins are handled twice daily, and pressed for half an hour each time; after this the decoction is renewed, and the same course followed as when in the first bath, the time in the second case being likewise a week. After this the

skins are taken out and dried in the ordinary way, when they are fit for currying with the empyreumatic oil which gives this kind of leather the virtues so much desired. In the execution of this part of the work, the ordinary course is followed, fish oil being first used, with the requisite shavings, stretchings, and pommellings, to render it pliable. The leather is then grained by passing it between rollers weighted to the proper degree by levers or some analogous means, and having on their surfaces raised threads parallel to, and intersecting one another, to give the intended grain. After this the skins are dried to the proper degree, and then oil of the birch, or *Russian* oil, is spread over on the flesh side. The color peculiar to this kind of leather is then laid on, and in this state the skins are repeatedly exposed to the rays of the sun, in order to make the color penetrate into the pores; they are then well pommelled and slicked with the *lunette* or circular knife on the beam, and finally worked with a hard brush on the hair side. The red color of Russian leather is produced with alum and a decoction of Brazil and sandal wood, and the black with a solution of sulphate of iron—copperas—and sandal-wood.

In impregnating with the oil, great care is necessary to have the absorption equal; at the same time, too much oil must not be employed, lest it might pass through and stain the grain side. This is especially to be guarded against when operating on small delicate skins; when it is desired to confer some of the properties of Russia leather upon undyed, or Morocco leathers, the quantity of birch oil necessary is very small.

The method of manufacturing the oil of birch in Russia is somewhat rude. The white membranous matter of the bark of the tree, deprived as much as possible of woody fibre, is introduced into an iron vessel of suitable dimensions till the latter is full, when the cover, of an exterior convex shape, is fixed on. From the middle of this lid an iron tube issues, and enters to about three-fourths of the depth of another iron receptacle placed over the former. The edges of both vessels are well bolted and screwed together, and the whole inverted, so that that charged with the bark is uppermost, and the empty one beneath. In order to condense the oil as much as possible, the empty receptacle is buried in the ground to keep it cool; the top one is then secured by a coating of cement made of clay and sand, and when dry, surrounded with a wooden fire till it is raised to a red heat, which is continued till the distillation is completed. When the two vessels are detached, the upper one is found to contain a light friable charcoal, and that serving as a condenser, a brown oily empyreumatic liquid, possessing a very strong odor, some tar, and pyroligneous acid. The product, being depurated from tar and acid, is retained in well-closed vessels for the use of the currier. In France, the bark is distilled in copper vessels, and the heavy oil condensed in a tube passing through water, or an ordinary worm. About six per cent. of the bark passes over, but the oil, which is highly colored, is not very abundant; by rectification, however, it can be obtained almost colorless, in which state it is better adapted for oiling fine white leather than the original product, as it does not leave any stains.

It appears from the experiments of CHEVREUL, PAYEN, and CHEVALIER, that the principle to which the above oil owes its odor and other qualities, is a white pulverulent substance soluble in alcohol, which they call *betulin*; it is volatilized by heat, and condenses into crystalline needles; thrown upon live coals, it gives off thick white vapors similar to those emitted by Russia leather under similar circumstances, but more agreeable.

Hungarian Leather.—By the method long known and practised in Hungary, and latterly in France and other countries, leather is prepared in a rapid way, and without the aid of tannin—mineral salts being substituted together with other agents. The substance most generally resorted to for combining with and preserving the tissue of the skin, in other words, for converting the latter into leather, is sub-chloride of aluminum, produced by the decomposition of ordinary alum by common salt. This preserves the skin; and another kind of tanning process, with oil or tallow, gives the leather suppleness, and prevents it from forming a hard body. In this manufacture, the influence of the season, air, or other agents which affect the labors of the ordinary tanner are not felt, in consequence of the brief time it occupies, and the nature of the process. The requirements for carrying on the business are fewer and more simple than those of the ordinary tanner. They consist of a shed erected on the banks of a stream, wherein the beams for pairing, fleshing, and unhairing are arranged, and the knives, scraping stones, and other tools kept. A boiler and furnace for preparing the alum liquor is fitted up in one corner, besides which are two larger tubs for immersing the skins, together with a number of smaller ones. The other division of the factory, where the oiling is done, consists of a room six and a half feet high, by sixteen and a half square, capable of being rendered perfectly tight. One corner of this chamber is occupied with the furnace, over which is placed a copper pan capable of containing one hundred and eighty pounds of tallow; the sides are occupied by tables, whereon the skins are greased; the centre has a stone slab three feet and a quarter square, and on this an iron grating is fixed, whereon charcoal is burned for the purpose of flaming or heating the hides, as will be mentioned afterwards. The upper part is furnished with poles for hanging the skins on.

In tanning or preparing Hungarian leather, the principal preliminary processes are analogous to those already described, only that instead of liming for the depilation, the hair is carefully shaved off—that is to say, the skins are well washed, cut in halves, shaved, and steeped for twenty-four hours in the running stream.

The greatest care must be exercised, and the most expert workmen employed for fleshing, paring, and shaving off the hair, lest the skin should be injured, and at best the operation is tedious, so much so, that one man can work no more than a dozen or fifteen skins in a day. The shaving and washing being completed, the hides are passed through the first alum bath, composed of six to seven pounds of alum, and three and a quarter to four and a half pounds of common salt dissolved in eight gallons of water, for every hide of seventy-five

to eighty-five pounds weight. After raising the temperature of this solution to about 120°, or a little higher, the hides or sides are arranged in parcels of three or four in each, and deposited in two large tubs already mentioned, the hair side being uppermost.

As much of the liquor as will cover them is now poured in, and a workman stamps or treads them out, passing backwards and forwards till the piece exposed to this treatment is sufficiently worked, after which it is rolled up, and the same operation proceeded with till every one of the parcel has received the proper treading. After this, the partly-spent alum liquor is returned to the boiler; and as soon as its temperature is raised, another quantity is ladled into the vat, and the pieces of skin tramped out as above. A third and fourth treading is given, using warm liquor each time, after which they are folded up and deposited in a series of small tubs, about two feet high and eight inches in diameter, and the spent alum menstruum poured over them. They remain in these tubs for eight days, or longer in winter, being handled every day, and the liquor freshened. At the end of this time the strips of skin are taken out and shaken, or stretched, to remove creases, and then treated a second time exactly as in the first aluming, save that they are left only twenty-four hours in the small tubs, in contact with the saline water. After taking them out, they are laid one upon another on an inclined plane, in order that as much of the alum liquor as possible may run back into the vat. When thoroughly drained, the ends are pierced at the corners, and wooden rods or laths thrust through; then one of these is laid on cross-beams, and the piece of hide distended permitted to be freely suspended. Here they remain for eighteen hours, and then they are taken down, laid on the floor, and the workman, by folding and stretching, removes the wrinkles and creases; this done, they are laid one upon another, and left so for two days, then hung up by the laths on the cross beams till thoroughly exsiccated.

The dried skins, before they are fit to receive the oil, must be softened by treading them upon an inclined plane, suspended, as shown in the figure annexed, by upright and cross pieces firmly bound together. The strip of skin is laid doubled on this plane, and a smooth stick placed in the fold, and the workman, laying hold of the cross handrail, tramps upon the skin, and, by a shuffling motion of his feet and body, causes every part of it to be pressed and smoothened by the roller. To render the process more effectual, he wears thick-soled shoes. He continues the work of tramping and shuffling the stick about in the fold of the skin, till the latter becomes as soft and pliant as it is possible to make it. Each strip or piece is thus worked, and subsequently exposed for a short time, to be dried if necessary. After this

Fig. 352.

desiccation, they are again slightly trodden in the same manner as before, to erase any contractions and wrinkles, *et cetera*.

They are now fit to be greased, and, therefore, are submitted to this operation. The boiler, which occupies one corner of the air-tight chamber wherein this work is done, is three-fourths filled with tallow, fish oil, or whatever else is used for saturating the skins, and the whole heated by a fire outside the walls of the apartment. When the temperature stands a little above the melting point, a short-handled mop or dauber is dipped into it, and the fat spread equally in this heated state over the flesh side, after which the strip is turned, and the hair side brushed over with what remains in the dauber. Those which are first greased are laid upon one another, flesh side upwards, successively, till the entire number have been treated. They are allowed to remain for a time, to enable them to absorb the fat as much as possible before *flaming* them. For this purpose, a fire of charcoal is lighted on a grate, constructed on bricks in the centre of the room, and whilst it is being lighted, the workmen, two in number, leave, closing the door tightly after them. As soon as the charcoal is thought to be incandescent, they open the door to allow the carbonic acid to escape, and then enter, and taking the top strip of the pile, each by one end, expose it, flesh side downwards, to the glowing fire, holding it at some distance, and at the same time stretch it in all directions. The first so treated is laid on an adjoining table, and the others as they have passed through the same operation are piled upon it, the whole being covered with cloth as a protection against cold draughts and the unequal effects of the fire. This treatment aids in the absorption of the oil, and the stretching given at the same time improves the product. After an interval of an hour, the hides or sides are deprived of the excess of fat by wiping them. They are then thrown across poles to dry, flesh side outwards. The last exposure gives them a consistency, owing to the combination of the fat with the tissue and the saline matter united to it. The direct rays of the sun and an increased heat are to be avoided in this final airing, as neither is conducive to the improvement of the article. After this airing the sides are weighed, stamped, or marked, and put up for the market.

Hungarian leather prepared in this way, without the intervention of acids or alkalies, fermentation, or other matters and processes that are known to be more or less injurious when making leather with tan, preserves all the tenacity and body of the skin, combined with strength and great suppleness; for which, and for its tractive power, it is much used by saddlers and harness-makers.

TAWED LEATHER.—In the preparation of this kind of leather, the conserving agent resorted to is a subsalt of alumina, just as in the manufacture of Hungarian leather. The skins most generally treated are those of sheep, lambs, and kids, together with a few other light varieties. Generally the preliminaries required are performed in the ordinary way, only the skins being more tender, demand greater vigilance to preserve them from injury. They are well soaked in running

water for the purpose of cleansing. If dry, as in many cases, this steeping must be assisted by working or *breaking* them upon the beam with the back of the fleshing knife on the inner side. After another rinsing, the skins are smeared with cream of lime, or a mixture of lime and orpiment, gas lime, *et cetera*, on the flesh side, and then laid together in pairs, the hair side being outwards. According to the efficacy of the depilating agent employed, the time of the slacking of the skins extends from twenty-four hours to several days. However, as soon as it is found that the hair yields, it is separated, not in the usual way, but by plucking it out by sharp pincers. This being done, the skins are smoothened by a roller or some such means; then re-immersed for a short time in a weak lime-vat, from which they are removed to another steep, and left to soak therein for ten to fifteen days, with occasional handlings or examinations. When taken from the last vat, they are ready to be submitted to the bran vat or ferment, similar to those already mentioned, the proportions being forty pounds of bran in twenty gallons of water. In this mixture the skins remain for a period of a fortnight or three weeks in winter, according to the lowness of the temperature; but in summer, when the weather is hot, two or three days suffice to raise them sufficiently.

In any case, as soon as the skins sink in the menstruum—an occurrence which may be hastened by stirring them frequently—the action of the steep is known to be completed, and the skins are taken out and submitted to the first alum or *white bath*. This is composed of a mixture of thirteen to twenty pounds of alum, and three to four and a half pounds of chloride of soda dissolved in boiling water, the solution being afterwards diluted so as to saturate one hundred sheep skins. In summer the proportion of salt is increased, in order to preserve the skins from any injury of a putrefactive nature. The working of the skins is done in parcels, as in the preparation of Hungarian leather, each parcel being passed successively through the bath; after which, the whole are immersed for ten minutes. In some tanneries, instead of simply steeping the skins in the latter bath, the alum liquor is introduced at the proper degree of warmth, together with the skins, into a cylindrical vessel with means for revolving attached, and worked for the necessary time. The intimate contact of the skins with the whole of the liquid in this case promotes, it is said, the combination of the basic aluminous salt with the tissue, much more completely than is done in the other mode. The skins intended to remain white are then put into a paste, made by adding to the alum bath from fifteen to twenty pounds of wheaten flour, with gradual stirring, and the yolks of fifty eggs well whisked, and the whole contents of the bath well blended by brisk stirring. The skins are passed singly through this menstruum, which is about the consistence of honey, and afterwards the whole hundred are immersed, and allowed to remain in it during the night. After this they are taken out, and suspended on poles to dry, and left exposed for this purpose from eight to fifteen days, according to the weather, being occasionally stretched both ways. When sufficiently dry,

they are worked upon the *softening iron*, by which process any unevennesses are removed, the whiteness is developed, and the whole uniformly stretched. They are next fixed on hooks, where the stretching goes on—more, however, in the breadth than in the length of the skin—being worked during the period of their thorough desiccation with the stretching iron. In some cases the dried skins are submitted to a polishing process, by rubbing them with pumice and giving the final gloss with a smooth flat-iron.

These operations suffice for the preparation of tawed leather, in which the alum salt serves as tan, and the albuminous matter impregnated with it in the farinaceous bath supplies the place of oil or fat in giving greater suppleness and impermeability to the preparation than it otherwise would possess. Skins are frequently tanned by this process, with the hair retained and dyed. All the operations necessary in this case are the same as have been just detailed, with the exception of those that aim at the removal or softening of the hair, which are carefully guarded against. When dyed rugs are prepared, the wool is colored, previous to the commencement of the tawing, by any of the ordinary methods.

Tawed leather is occasionally colored. The tinctorial matter, whatever it may be, is laid on the grain side in a moistened state and while the skin is yet damp, and worked into it by means of a stretcher, after which treatment the polishing and smoothing take place.

OIL OR CHAMOIS LEATHER.—This article takes its name from the skins of the *chamois*; but, although the term is still retained, those of sheep, deer, lambs, and the thin portion of split hides and skins, are now converted into it. It is different from any of the varieties hitherto described, because neither tannin nor mineral matters enter into its formation; the conservation being entirely effected by means of oils and fats. Further, the finest, as well as the coarsest quality known as *wash-leather*, receive precisely the same treatment, and consequently the difference they present is owing to the circumstance, that the finest skins are chosen for the former, whilst the inferior ones are made into the latter. In the last, sixteenth, and earlier centuries, the trade in chamois leather was much more considerable than at present; because, in those periods, it was extensively used for clothing, particularly in the armies. It is now, however, abandoned for this purpose, in consequence of its permeability, owing to which it readily absorbed moisture, and parted with it but slowly; qualities which kept the wearer in continual danger of cold and rheumatic complaints.

In the manufacture of chamois leather the skins are prepared by passing through the lime vats, scraping on the horse, *et cetera*, in the ordinary way; and when these preliminaries are effected, and the lime removed in the lactic acid or bran vat, as much as possible, they are subjected to the *frizing* operation. This consists in rubbing them with pumice-stone, or the blunt end of a round knife, till the grain is entirely removed, the surface softened, and an equal thickness obtained throughout. After this the skins are squeezed or pressed, in order to remove as much water as possible.

With this view they are placed in the trough of a fulling mill, such as is represented in Fig. 353, after the large excess of water has been expressed, and are there subjected to the action of the wooden hammers till they become nearly dry. When this happens, they are

Fig. 353.

spread out on the table to receive the first charge of oil. That employed is usually cod oil, although any kind of animal oil is made to answer. When this has been sprinkled upon them, they are rolled up in bundles of four each, and then submitted to the action of the mill for a period varying from two to four hours, or until the oil has united or become absorbed in the pores of the skins. They are then taken out, unfolded, and exposed to dry for a short time; then a second oiling is given, followed by a fulling. It is necessary to repeat these operations several times, to insure the proper saturation of the skin fibre. However long the action of the fulling mill is continued, it is necessary to bring the aid of heat into requisition before the combination of the fatty matter with the skin is completed. Heat is applied generally by suspending the skins in a close chamber, furnished with steam pipes, or warmed with a stove to the proper degree. It is supposed that during this heating a fermentative change takes place, by which certain deleterious matters are destroyed, and the skin is afterwards better able to resist putrefaction, in addition to the more complete saturation of every part.

The greater dilution of the oil by the increased temperature of the stove-room causes part of it to exude on the surface, and this must be removed by immersing the skins in a wash or bath, made with soda or potassa in water, and of such density as will not dissolve the fibrous tissue. The skins are steeped for an hour, and handled in this bath, after which they are wrung at the peg and dried. To give the finish, the leather is worked with the stretcher on the table, then on the horse, and lastly, passed between rollers to give it the polish. The buff-color which generally, though not always, distinguishes chamois leather, is given by immersing the oiled skins in an infusion of oak bark,

and afterwards wringing, drying, *et cetera*. The tannin reacts here as a dye, and not as a tanning agent.

For supplanting the hand labor in *frizing* and other operations, NISBET has patented machinery by which rough bodies and knives, mounted on revolving cylinders, are made to rub against the skin. By this means a regularity in the thickness and texture of the skins is obtained, which could hardly be gained by hand unless more than ordinary attention were bestowed upon the work, while the time is curtailed to one-tenth of that required by the old method.

MOROCCO LEATHER.—*Maroquin*, French; *Saffian*, German.—Before the eighteenth century all morocco leather was imported from the Levant; but of the way in which it was prepared, nothing was publicly known till the account of GRANGER appeared in 1735. About the middle of the last century a manufactory was established at Paris, the first of its kind, in the Faubourg St. Antoine; this in a few years was followed by another; and from the impetus given by an increased demand, the trade continued to extend until, at the present time, there are several manufacturers of this article to be found in the different countries of Europe, and in the United States of America. Morocco is commonly known as a colored leather, having an indented or wrinkled fibrous appearance. The genuine or true variety is made from goat skins; but another kind, known as *imitation morocco*, is manufactured from sheep and lamb skins. As stated in the introduction, in connection with the subject of skins, the best kinds for this purpose come from Switzerland; but the English manufacturer draws upon other countries for his supply, such as Germany, Memel, Mogadore, East Indies, Cape of Good Hope, and several others. Compared with sheep skins, those of the goat have a closeness of fibre, a body, and strength that render them much superior in point of appearance and durability. In France, the Spanish goat skins are highly esteemed, and, consequently, a good many are imported from that country.

The skins usually come into the tannery in the dried state; and the operations required to render them as soft and pliable as fresh ones, and likewise to deprive them of epidermis, hair, and particles of flesh, are so similar to those already described in connection with the ordinary tanning processes, that a very brief account of the method of treatment will be sufficient. The dried skins are first immersed in water till they are sufficiently softened, and after this in a fermentable bath of a weak nature, such as has been used for a previous operation. Here the softening is considerably assisted; but it is necessary to watch its effects with much attention, lest it might be productive of injury to the skins. When it is thought they have acquired the proper degree of pliancy, they are worked on the flesh side with the disc or circular knife, to separate the fatty and fleshy matters, and likewise to remove the creases produced in the drying. This done, they are next submitted to the depilating agents, which consist of a number of solutions of lime, increasing in strength from the first to the last. Scarcely any difference exists between this part of the process and that which is followed in tanning upper-leather; but as the retention of lime or fatty matters is still more objectionable in skins

intended for morocco, owing to such matters being liable to produce spots or stains in the color applied at a future stage, greater attention and labor are required for their complete removal; hence after the unhairing, the fleshing, and paring of the head and leg parts, and the short steeping in lime-water which is usually given after this, the trimmed skins are introduced into a wooden cylinder moving upon an axis, and having interiorly a number of wooden pegs rounded at the end. This fulling machine is half filled with clean water, and, being charged with as many skins as it will conveniently hold, it is set in motion. By the action of the pegs and the movement of the skins and liquid, a considerable quantity of the lime is separated, the water of the cylinder being frequently renewed. To complete the depuration from lime, it is necessary to submit the skins to a bath of fermented bran or flour disseminated in water, or to one formed of dogs', pigeons', or pen-fowls' excrements, and called as usual the *bate* or *pure*. After being in one or other of these, as the case may be, from twelve to twenty-four hours, according to the strength and temperature, they are taken out and scraped on the beam on both the flesh and grain side, and examined for the purpose of rejecting those which are inferior or in any way damaged. In some instances, instead of the bran vat or *bate*, a solution of honey or a decoction of figs has been employed, together with a little salt, to steep the limed and unhaired skins in, on the principle of TURNBULL's patent, when the saccharine matter enters into a readily-soluble combination with the lime, and washes out with facility. In either case the more perfect skins which are set aside for the better quality of morocco, are prepared for the operation of dyeing, which with them generally takes place before the tanning, whilst the second and third qualities are colored after the tanning is executed.

Red Morocco.—The perfect skins are placed together two by two, so that the parts of one correspond with those of the other, the flesh side of each being inwards, and then sewed round the edges sufficiently close to retain the air, which is afterwards blown into them so as to swell them into a kind of bag. In this state, on being plunged into the mordanting liquor, only the surface destined to be dyed takes up the substance of the mordant, and consequently of the dye afterwards, and therefore no waste is incurred. The mordants are generally alum, chloride of tin, wine-stone, or such substances; but the tin-salt gives the finest shade of color. The mordant liquor of either of these, sufficiently diluted and warm, is put into a suitable vat or vessel, and the swollen skins immersed for a few minutes in it, then withdrawn and allowed to drain where the drippings may flow back to the vat. Afterwards they are worked on the beam with the view of giving them a grain, and expelling the excess of liquor more completely. This treatment prepares them for the dye, which is usually cochineal, as it gives the brightest color of any. For each dozen of skins from twelve ounces, or less, to sixteen is taken, according to the size. It is finely powdered, and suspended in water to which cream of tartar or some alum has been added. The whole is then boiled for

some time in a copper, filtered through a fine cloth, and divided into two equal portions to give two successive immersions. The skins sewed up thoroughly are placed in the tun with half of the dye liquor, and well agitated for about half an hour, after which time the liquor is replaced by the second portion, and the motion of the contents prolonged for a further half hour, when the dyeing will be completed. The skins are now taken out and submitted to the tanning operations, which are the same as will be presently described. Finally, the sewing is ripped; the skins—now tanned leather—well rinsed in fresh water, worked on the beam to render them supple and remove creases, dried, pommelled, slickered, and grained in the ordinary way. Sometimes the dye is brightened by passing a sponge saturated with a solution of carmine in ammonia over it, after the partial drying that follows the tanning and rinsing, *et cetera*. Also the skins are wetted with a decoction of saffron, in order to obtain a shade of color approaching to scarlet.

Morocco of other shades of Color.—Morocco leather of other colors is tanned previous to fixing the dye upon it. After the depilation and *bating*, or *branning*, as the case may be, the pelts are placed in a revolving cylinder with the tanning agent, which is always sumac, and a proper quantity of water slightly heated, and the agitation kept up for some time, by means of connecting or driving bands, and drums on the axis of the cylinder, and on the main or other shaft of the engine. The first tanning is given with sumac, partly or half reduced, and suspended in water, so as to form a thickish paste, and finished by substituting a new bath of fresh sumac; the motion of the cylinder being maintained whilst the skins and tanning agent are in contact. With this method, the formation of leather is very rapid, requiring only twenty-four hours. The tanned skins are now removed from the cylinder, rinsed, so as to clean them from the sumac, and exposed in the drying-room; and when the assimilated water is removed, they may be stored, or at once submitted to the process of dyeing, according to the requirements of the tanner. Another method is also much followed, as well with skins that have been dyed red as with those not so treated; it consists in employing a decoction, or *ooze* of sumac, and filling the skins with it, they being sewed two and two together for this purpose, having the flesh sides inwards, as already detailed. A quantity of powdered sumac is then introduced into each through the aperture, and afterwards a decoction of the tan; the opening is now secured, and the bags thus formed are deposited in a large tun, likewise containing a solution of sumac tan, as represented in Fig. 354, where they are floated and moved about, so as to expose every part of the skin to the action of the tanning agent. When the solution and tan in the leather bags are supposed to be exhausted, the bags are taken out and laid on the rack adjoining the tun, where they drain for some time; they are again filled with the strong solution, floated and moved about in the large tub as before, till the tannin has entered into combination. They are now removed from the tun, placed to drain, till the contained liquor is emptied into the tun, ripped, and cleaned from the

debris and impurities of the tanning material by thorough washing in cold water. Any wrinkles are removed by working on the beam before exposing them on the drying loft. During the desiccation, the skins shrivel so

Fig. 354.

much as to necessitate their immersion in water for some time, or the fulling of them in a machine such as is used for making chamois leather, tepid water being used. After fulling, several workings on the beam are given, as well on the hair as on the flesh side, in order to remove the excess of sumac. One of these workings consists in beating the tanned skin upon a table studded with round-headed pegs, with the view of breaking up the small fibres, which otherwise, by their contraction or expansion, would cause the articles made of this kind of leather to become deformed. They are placed one upon another, flesh side inwards, and stitched round, or indented with a blunt knife round the border, so as to keep them temporarily together, whilst they are being handled in the color-vat, and to prevent the dye being deposited on any other part than the grain side. For all the shades of color, with the exception of blue and black, a steep of Campeachy wood is employed, heated as hot as the hand can bear; this is put into a rectangular vessel, and the two skins laid into it carefully, and pressed and worked, so as to induce the penetration of the liquor, but not to remove them from one another. Several immersions are required with fresh coloring matter, till the proper tint is obtained. Much practice and attention are necessary to immerse and work the skins in the dye-vat, in order to stain them efficiently, and prevent the color running on both sides.

Black morocco is prepared by applying with a brush, on the grain side, a solution of sesquiacetate of iron. The azure tint is given by means of the cold indigo-vat, or with Prussian blue; violets and purples are produced by giving two coats of blue, and afterwards passing the skins through a bath of cochineal, the strength of which is regulated according to the shade required; yellows are obtained by working with quercitron root, finely ground and digested to abstract the color; this dye is very brilliant and stable. By modifying the work and multiplying the immersion and baths, any shade intermediate between those described can be obtained.

The dyed skins are now placed on the plate of the hydraulic press, and the excess of dye-stuff expressed, after which they are worked on the beam, to remove creases or wrinkles, and dried; first spontaneously in

a current of cold air, and afterwards in a heated atmosphere. Before being perfectly dry, however, they are worked with the knife, slicker, and pommel, as in the operation of currying, whereby they acquire suppleness and equality of substance throughout. They are then well polished, and the peculiar grain of morocco leather given. The latter is done sometimes by hand, but more generally by machinery.

Rollers, having raised parallel straight or diagonal threads, give the indented or wrinkled appearance, which distinguishes this kind of leather. When the skins are merely tanned, as when intended for the shoemaker, and then curried, the operations of the last process are such as are applied to delicate calf skins, only that as the goat skins are so much thinner, much greater care and delicacy of manipulation must be exercised in all cases.

SKIVER AND ROAN.—*Skiver* is a leather prepared from sheep skin and sumac, like imitation morocco, only the skins are split by machinery. In tanning the sections, however, the practice differs from that followed when preparing the morocco leather, inasmuch as the sewing of the skins into bags is omitted, the extreme thinness of that intended for skiver adapting it to combine with the tan more readily when spread out in the ooze. *Roan* is sheep skin tanned like morocco leather in all its details, but wanting the grain given to the latter by the grooved rollers in the finishing processes.

Before closing this article, it may be proper to give a short notice of two other materials, which, though not leather in the proper sense of the term, are nevertheless analogous to it; these are Parchment and Shagreen. Both are prepared from the same kinds of skin, but generally the stronger and coarser kinds are reserved for the latter.

PARCHMENT.—This article, undoubtedly of Eastern origin, is said to be the invention of EUMENES, king of Pergamus, in Asiatic Turkey, who reigned about 200 years before CHRIST. It was much used as a substitute for the papyrus, owing to its durability; and even at the present time it is the article in general use for valuable writings, such as deeds, wills, and the like. The fine parchment used for such purposes is manufactured from the skins of young calves, kids, still-born lambs, sheep, and goats; but when intended for coarser purposes, such as drum-heads and the like, those of older calves, wolves, asses, and *he-goats*, are taken. Soaking or fulling, liming till the hair is softened, scraping, fleshing, and washing, prepare the skins for the process of conversion into parchment, properly so called. It consists firstly in stretching the cleaned pelt upon a circular hoop, or more generally upon a stout rectangular frame, furnished with holes, pins, and screws, or skewers and cords, for exerting any required tension. This machine is usually fixed against the wall of the building, for the purpose of facilitating the scraping and rubbing of the drawn skin, after it has been sufficiently extended by the pins and skewers. The preliminary scraping effected with a double-edged semicircular knife, formerly referred to, removes adhering flesh and other extraneous matter. After the fleshing, the frame is turned, and the grain side carefully rubbed with the blunt edge of the knife, to

throw off the exudations of dirt and moisture. Then follows the *grinding*, which consists in sprinkling the flesh side with finely-powdered chalk, or slaked lime, and rubbing with a piece of pumice-stone, the face of which is previously flattened upon a sandstone. By this operation, a further portion of the assimilated moisture is taken up. A slight rubbing with the pumice-stone is then given on the grain, but no lime is used, and afterwards the drying is allowed to go on gradually out of the sun's rays. In cold weather, the freezing of the moisture in the skin would be injurious; and is, therefore, carefully guarded against by keeping the temperature of the room above 32°, or by protecting the skins with cloths. Towards the completion of the desiccation, the skewers are further tightened. Finally the white appearance given by the lime is removed by careful rubbing with the woolly side of a lamb skin. Should grease stains be now detected, it is necessary to immerse the skin anew in a lime-pit for eight or ten days, to remove them; this induces the formation of a lime soap with the fatty matter, and consequently the deletion of the spots. The pelt is again stretched on the *horse* or frame, and dried, and then transferred to the *scraper*, who mounts it upon a frame like the last, the tail end downwards, and stretches it with cords only, on a support of well-extended crude calf-skin. Here it is carefully pared with a larger and sharper knife, but similar to the one used for *fleshing*, to remove inequalities, and then scraped on the grain or outside, till a perfectly even, smooth surface is given. Whatever is wanting in this operation, is remedied by a further rubbing with a very fine-faced piece of pumice-stone on a cushioned support. Any defects in the skin, such as holes and the like, are removed by carefully paring round the edges of the injured part, and tastefully patching suitable pieces on with gum-water.

The green color of parchment is given by spreading with a brush a solution, made with thirty parts of crystallised acetate of copper and eight of bitartrate of potassa in five hundred of rain or distilled water, four parts of nitric acid being added to the mixture when cold. It is necessary to moisten the skin before applying this dye. Finally, the lustre is given by rubbing the surface with a solution of albumen or gum arabic.

SHAGREEN.—The article known under this title is very analogous in its nature to parchment, and consequently is not a true leather. Like parchment, it was originally an Eastern preparation, and is still principally obtained from Astracan and Asiatic Russia. From the accounts obtained of the manufacture, it appears that only the hides of horses, asses, and camels, are appropriated to its production, and of these only the small strip from the crupper along the chine to the neck is used.

The strips, cut out of the proper size, are steeped in water till the hair softens and gives readily, when it is removed by scraping; they are again steeped and worked by the *flesher*, till all matter extraneous to the skin is separated, and the skin itself is reduced to the proper thinness. They are now mounted on the *herse*, or horse, and stretched thoroughly, being occasionally moistened to favor the stretching.

As soon as this has been carried sufficiently far, the strips of skin are placed on the floor and covered on

the grain side with the seeds of the *alabuta* or goose-foot—*chenopodium album*. A covering of felt is then laid on, and the seeds are pressed into the skin by trampling on them, or by the use of mechanical pressure. The skins, still bound in the frames, are then dried, till the seeds begin to drop, when the latter are shaken off. At this stage the skins appear dry, horny, and deeply indented. They are next placed on a padded horse, and shaved till the indentations caused by the seeds become very shallow and of uniform depth, after which they are steeped in water and then in a hot alkaline lye, and piled one upon another whilst in a hot moist state. During the time they are so left, the compressed parts swell out, forming as it were embossed balls on the skin, and thus constitute the peculiar appearance of this preparation. Shagreen is dyed of various colors; red is obtained with a decoction of cochineal, in the same way as morocco; blue by the cold indigo vat; black, by steeping the skin, or brushing on the side intended for the dye, a solution of tannin, and afterwards one of sulphate of iron—copperas; and green, by moistening with a dense solution of chloride of ammonium—sal-ammoniac—and sprinkling the part so moistened with copper turnings and rolling up the strip, keeping the grain

side inwards. The ammoniacal salt dissolves a portion of the metal and forms a subsalt with it, which enters into combination with the skin, and gives a bright hue. To finish the article, the dyed strips are carefully greased and worked in hot water, then rubbed with blunt tools and dried.

Shagreen of an inferior quality has been made from sheep, goat, horse, and even fish skins; the treatment they receive is analagous to that already described, but for the most part, where the skin is weak, a slight tanning is allowed before shaving, and the skin is stretched more in the direction of its length than crosswise. The grain is given by pressing the prepared skin on warm copper plates, engraved so as to imitate the appearance of the genuine shagreen.

In preparing this account of the leather manufacture, much of the information, besides what has been derived from private sources, has been obtained from Doctor MORFIT's able work on Tanning, KNAPP's Technology, SCHUBART, DUMAS, PARNELL, SULLIVAN, the Catalogue of the Irish Industrial Exhibition, and other authorities.

STATISTICS.—The following table expresses the imported quantities of the principal tanning materials in 1849 in hundredweights:—

MAGNESIA.—English and French; *Talkerde*, *Bittererde*—German.—This is one of the primitive earths, and was first discovered by Sir HUMPHREY DAVY to be the oxide of a metal which he designated magnesium, and which LIEBIG has proposed to prepare by calcining a mixture consisting of chloride of magnesium and chloride of ammonium. Very great precautions are requisite in this method, and especially the most complete desiccation. On the mixture being dried, the ammoniacal salt begins to volatilize; the mass is to be pulverized and reheated, in order to expel the last traces of moisture. The difficulties which this operation presents, and the errors to which it frequently gives rise, induced BUNSEN to seek for a less doubtful and convenient method of procuring this singular metal. Now, the chloride of magnesium is decomposed with the utmost facility by the galvanic current when it is liquefied by heat. A few elements of a Bunsen's battery suffice for obtaining in a short time several grammes of product.

Take a platinum crucible equally divided by a vertical diaphragm for half the height of the vessel; this diaphragm is necessary for the protection of the mag-

nesium, in proportion as it is released from the action of the chlorine, which is liberated at the positive pole of the battery. The crucible is closed with plugs of fire-clay, traversed by two charcoal stems constructed as for batteries. These stems form the poles; that which corresponds to the negative pole is hollowed with cavities or channels for the purpose of retaining the magnesium, which, if this precaution were omitted, would float on the bath of fused chloride of magnesium, in which it would be burned.

Magnesium is silvery white, has a crystalline and sometimes fibrous fracture, is malleable, ductile, and fusible at a dull red heat; it is sufficiently hard, however, to work under the file and chisel. Its specific gravity, as determined by various experimenters, ranges from 1.87 to 2.24. Dry air produces no action upon it, but in damp it is tarnished, and covered with a layer of magnesia. At a red heat it consumes with a brilliant white flame. Cold water is only very gradually and with difficulty decomposed by this metal, which is quickly dissolved in acidulated water. Finally, it ignites when brought into contact with hydrochloric acid, whilst concentrated sulphuric acid dissolves it with difficulty.

Oxide of magnesium, or *magnesia*, is a fine, light, white powder, void of taste or smell. It requires for complete solution more than five thousand parts of cold, and *thirty-six thousand* parts of boiling water. Its specific gravity is 2.30. It is fusible only by the heat of the oxyhydrogen blow-pipe. Magnesia changes the purple infusion of red cabbage to a bright green. It attracts carbonic acid very slowly from the air. Its equivalent is 20, and its composition as under:—

		Centesimally.
1 Eq. of magnesium,.....	12	60.00
1 Eq. of oxygen,	8	40.00
1 Eq. oxide of magnesium,.....	20	100.00

This oxide occurs in nature as carbonate, forming immense masses of rock in various parts of the globe; also associated with carbonate of lime under the forms of dolomite and magnesian limestone; and as sulphate of magnesia—Epsom salts—occurring in many saline springs.

It is best obtained pure by heating the carbonate to redness; but it is also procured by precipitating with potassa or soda the sulphate, filtering and well edulcorating the deposit with distilled water.

Carbonate of potassa or soda causes a precipitate in solution of magnesia; but carbonate and sesquicarbonate of ammonia, owing to the formation of a soluble double salt, gives only a partial precipitate; and, for the same reason, oxalate of ammonia does not occasion any turbidity in liquids containing magnesia. By this last character the earth is separated from lime. The most delicate test for magnesia in a solution is to add, first, carbonate of ammonia, then phosphate of soda— 2 Na O, HO, PO_5 —which forms an insoluble double phosphate of magnesia and ammonia— $2\text{ Mg O, NH}_4\text{ O, PO}_5$ —in the form of a dense crystalline powder. It will be at once seen, that in the above change the ammonia merely replaces the water in the phosphate of soda. The salts of magnesia are isomorphous with those of oxide of zinc.

Physiological Effects.—When taken inwardly, magnesia neutralizes the free acids contained in the stomach and intestines, and forms therewith soluble salts.

As an *antacid* it is as efficacious as the alkalies, while it has an advantage over them in being less irritant and not caustic, and thereby is not apt to occasion any derangement of the digestive organs. It may be employed to neutralize acids introduced into the stomach—as in cases of poisoning by the mineral acids—or to prevent the excessive formation of, or to neutralize when formed, acid of the animal economy. Thus it is administered to relieve heartburn, arising from, or connected with, the secretion of an abnormal quantity of acid by the stomach; its efficiency is best seen in persons of a gouty or rheumatic diathesis, in which the urine contains excess of uric acid. It relieves the headache to which such individuals are not unfrequently subject. It is most efficacious in diminishing the quantity of uric acid in the urine in calculous complaints; and, according to BRANDE, it is sometimes effectual where the alkalies have failed.

As a laxative, magnesia is much employed in the treatment of diseases of children. It is tasteless, mild

in its operation, and antacid—qualities which render it most valuable as an infant's purgative. Independently of these, HUFELAND ascribes to it a specific property of diminishing gastro-intestinal irritation by a directly sedative influence.

As a purgative, the dose for adults is from a scruple to a drachm; for infants, from two to ten grains. As an antacid, the dose is from ten to thirty grains twice a day. It is conveniently given in milk. Magnesia has been used with success as an antidote to arsenic. —*Pereira.*

The Editor will now describe cursorily those salts of magnesia which are of importance, and which are much used in the arts.

SULPHATE OF MAGNESIA.—This salt is found in certain mineral springs, as those of Seidlitz, Leydschütz, Egra, and formerly Epsom, in Surrey, whence the name *Epsom salts*. Dr. GREW first obtained it from the Epsom waters. It has had a variety of names, such as *bitter purging salt, sal anglicum, sal seidlitzense, sal catharticum*, and *vitriolated magnesia*. At the Lymington Salt Works, says PEREIRA, it is called *physical salt*, to distinguish it from common salt. Its presence in the above-named springs appears to proceed from the reaction of the sulphate of lime, held in solution, upon the magnesian limestone of the soil.

Sulphate of magnesia is also obtained by the action of sulphuric acid upon calcareous rocks rich in carbonate of magnesia, such as *dolomite*. The compound is calcined, and reduced to powder by being aspersed with water; it is then diffused through water, and sulphuric acid is added: sulphate of lime and sulphate of magnesia are formed, the one barely soluble in water, and the other very much so; consequently, they are readily separated.

Epsom salts are also extensively made from the bitter or mother-liquor remaining after the evaporation of sea water, and the separation of the chloride of sodium therefrom.

At Lymington, in Hampshire, sulphate of magnesia is manufactured from bitter during the winter months. The liquor is boiled for some hours in the pans used during the summer for the preparation of chloride of sodium. During the ebullition, some chloride of sodium deposits. The lighter impurities are separated by skimming, and the strong solution is removed into wooden refrigerators, where, in a day, one eighth part of crystals of sulphate, called *single Epsom salts*, or *singles*, are deposited. These are drained, dissolved, and recrystallized; they are then termed *double Epsom salts*, or simply *doubles*.

At Monte della Guardia, near Genoa, sulphate of magnesia is prepared from schistose minerals containing sulphur, magnesia, copper, and iron. PEREIRA states that the ores, after roasting, are converted into sulphates by moistening, *et cetera*. They are then lixiviated, and the solution is deprived, first of copper by refuse iron, and afterwards of iron by lime. At Baltimore, sulphate of magnesia is procured from the silicious hydrate of magnesia, or *marmolite*, by reducing the mineral to powder, saturating with sulphuric acid, and calcining the dried mass to sesquioxide of iron. It is then redissolved in water, heated with

sulphide of calcium to remove the remaining iron, and crystallized. By a second crystallization it is obtained nearly pure.

A very large quantity of sulphate of magnesia is manufactured at Newcastle-upon-Tyne. It is made from magnesian limestone, calcined and washed to separate the lime, then adding sulphuric acid, *et cetera*. Another mode is by calcining rough Epsom salts along with magnesia.

From Magnesian Limestone.—In England, says KNAPP, the sulphate is sometimes manufactured directly from magnesian limestone and sulphuric acid, in conjunction with other products. The carbonic acid produced by the action of the sulphuric acid is employed in the manufacture of bicarbonate of soda, while the mixed sulphate of lime and magnesia are thrown into large wooden vessels, fitted with a false bottom. Water is now poured upon the thick mass, and drawn through by the action of a pair of pumps, worked from an engine shaft in any convenient manner. In this way, the whole of the sulphate of magnesia is extracted with the least expenditure of water; and the solution, after being pumped into a reservoir, is allowed to filter through layers of sandstone and charcoal, to render it clear and bright. The menstruum is now concentrated by evaporation, and made to crystallize as rapidly as possible, in shallow wooden troughs lined with lead, in order that the crystals may be as small as possible, to meet the prejudice of the trade in this respect. The sulphate of lime left on the filter or false bottom is worked up in the manufacture of Venetian red.

The process, however, which is more generally pursued is as follows :—

Magnesian limestone is calcined in an ordinary lime-kiln, and repeatedly washed with water to remove as much of the lime as possible. The extent to which this is carried may be inferred from the following analyses, by RICHARDSON, of a sample of lime in its natural state, and after it had been calcined and washed :—

NATURAL.	
Carbonic acid, <i>et cetera</i> ,	47.12
Lime,	27.49
Magnesia,	22.22
Insoluble matter, alumina, <i>et cetera</i> ,	3.17
	100.00
WASHED.	
Water, <i>et cetera</i> ,	32.51
Lime,	7.34
Magnesia,	44.41
Insoluble matter, alumina, <i>et cetera</i> ,	15.74
	100.00

The limestone selected by the manufacturer for this purpose is soft, and similar to that known as *flexible*; such samples as have the appearance shown in the engraving—Fig. 354—do not usually contain so much magnesia.

From Refuse Alum Liquors.—In the manufacture of alum as conducted near Whitby, the *salts' mothers*,

Fig. 354.

according to RICHARDSON, contain in the gallon :—

	Grains.
Sulphuric acid,	2697.61
Sulphate of magnesia,	8190.40
Sulphate of alumina,	852.24
Sulphate of potassa,	3693.32
Sulphate of manganese,	106.06
Sulphate of nickel and cobalt,	traces
Sulphate of iron,	3026.67
	19286.30

Which, by crystallization, produces a crude sulphate of magnesia, called *Rough Epsoms*, and having the following composition :—

Sulphuric acid,	32.26
Magnesia,	15.35
Protoxide of iron,	1.73
Oxides of nickel and cobalt,	0.12
Lime,	0.09
Alumina,	1.33
Potassa,	0.83
Water,	48.29
	100.00

These rough Epsoms are mixed with the magnesian lime in such proportions that all the sulphuric acid, except that in combination with the potassa and magnesia, is taken up by the free alkaline earths. The mixture is then calcined in an ordinary reverberatory, at a dull red heat, which assists the transfer of the sulphuric acid, and raises the metals to a higher degree of oxidation, thereby insuring their insolubility. The calcined product is afterwards thrown into a large circular cistern, filled with water, and in which a pair of edge-stones are made to revolve by suitable machinery. By this arrangement, the large pieces are ground to powder, while the agitation produced by the motion of the edge-stones facilitates the solution of the Epsom salt.

The sulphate of magnesia liquor is subsequently clarified in the manner previously described, and crystallized in the usual hollow pans. When the liquid has drained off from the crystals, they are removed to a stove, and exsiccated at a low temperature. In this

dry state, they are thrown into a species of sieve or temse, which reduces still further the size of the crystals, and renders the whole of a more uniform appearance.

From Native Carbonate of Magnesia.—Mr. CHANCE has lately imported a very pure natural carbonate of magnesia from the Mediterranean, to which he adds sulphuric acid, and proceeds in the usual way for the production of the sulphate; and having, it is understood, secured the entire produce of the mine, he is likely to become a formidable competitor to the other manufacturers.

Another article which is manufactured to some extent, requires a passing notice, namely, the salt termed *Mock Epsoms*, which is simply sulphate of soda crystallized very rapidly in shallow vessels, for the purpose of adulterating the genuine article.

The sulphate of magnesia crystallizes in right prisms, which at 60° are soluble in their own weight of water. When exposed to the air, they effloresce, and are reduced to powder. The intensely bitter taste of this salt is well-known. It is composed of,—

Water,.....	51·22
	100·00

Mr. ALEXANDER S. STEVENSON informs the Editor that about two thousand tons a-year are made in Great Britain, and of this quantity the Jarrow Chemical Company of South Shields produce one half.

Hydrated sulphate of magnesia, $\text{MgO}, \text{SO}_3 + 7 \text{HO}$, crystallizes at the ordinary temperature, in four-sided prisms, with reversed dihedral summits or four-sided pyramids. They are doubly refracting, and their density is 1·70. When crystallized at a high temperature, the salt contains only six equivalents of water, and if crystallized below 32°, large crystals are the result, having twelve equivalents of water. If heated to 460°, sulphate of magnesia still retains one equivalent of water, but it becomes anhydrous beyond this degree of heat; hence the Editor represents its composition as follows— $\text{HO}, \text{MgO}, \text{SO}_3 + 6 \text{aq}$. The crystals are soluble in about three ounces weight of water at 60°, and in three-fourths their weight of boiling water—as given by TOMLINSON. One hundred parts of water at 32° dissolve 25·76 parts of the anhydrous salt, and for every degree above this temperature, the water takes up 0·26564 parts additional. It is somewhat remarkable that sulphate of magnesia is much more readily dissolved by hydrochloric acid than by water. Sulphate of magnesia is insoluble in alcohol. Pure crystals exposed to the air have a slight tendency to effloresce; the commercial article always deliquesces on account of the presence of more or less chloride of magnesium. Sulphate of soda is often used to adulterate the sulphate of magnesia; the fraud is easily detected by exposing a portion to the blowpipe flame. If any soda be present, the characteristic yellow color appears.

Annexed is the centesimal composition of the official Epsom salts:—

Physiological Effects.—In moderate doses, sulphate of magnesia is a mild and perfectly safe antiphlogistic purgative, which promotes the secretion as well as the peristaltic motion of the alimentary canal. It is very similar in its operation to sulphate of soda, than which it is less likely to nauseate, or otherwise disorder the digestive functions, while it acts somewhat more speedily on the bowels. It does not occasion nausea and griping, like some of the vegetal purgatives, nor has it any tendency to create febrile disorder or inflammatory symptoms; but, on the other hand, has a refrigerant influence: hence it is commonly termed a cooling medicine. In small doses, largely diluted with aqueous fluids, it becomes absorbed, and slightly promotes the action of other emunctories: thus, if the skin be kept cool, and moderate exercise conjoined, it acts as a diuretic. Dr. CHRISTISON mentions a case of supposed poisoning, in a boy of ten years old, by two ounces of Epsom salts. The symptoms were, staggering, imperceptible pulse, slow and difficult breathing, extreme debility, and death within ten minutes, without vomiting. More recently, an old man, a confirmed drunkard, was poisoned by imbibing several pints of beer drugged with sulphate of magnesia. He was seized with violent purging, and died within forty-eight hours. The quantity taken was not ascertained, but there is reason to believe the dose was large.

On account of the mildness and general safety of its operation, its ready solubility, and its cheapness, sulphate of magnesia is by far the most commonly employed purgative, both by the public and the profession. The only objection to its use is its bitter and unpleasant taste. To state all the cases in which it is administered would be to enumerate nearly the whole catalogue of known diseases. It must, therefore, be sufficient to mention, that it is excellently well adapted as a purgative for febrile and inflammatory diseases, obstinate constipation, ileus, lead colic, even incarcerated hernia, narcotic poisoning, *et cetera*. It may be used as an antidote in poisoning by the salts of lead and baryta.

As a purgative, it is usually administered in doses of from half an ounce to an ounce and a half; but if taken in the morning, fasting, a smaller dose will suffice. Sulphate of magnesia is extensively used by veterinary surgeons.—*Pereira*.

CARBONATE OF MAGNESIA.—This compound is known in the mineral kingdom as *magnesite*; it is found in Piedmont and Moravia, and also in North America, in veins of serpentine, accompanying the native hydrate. It also occurs in combination with carbonate of lime, with which it is isomorphous. Most of the calcareous rocks contain a small quantity of magnesia. In the species of marble called *Dolomite*, which occurs abundantly in the Alps, about forty per cent. consists of carbonate of magnesia; the marble itself is a double carbonate of lime and magnesia, $\text{CaO}, \text{CO}_2 + \text{MgO}, \text{CO}_2$. The magnesian limestone of Derby and Nottingham is

generally of a yellowish color; it dissolves less rapidly in dilute hydrochloric acid than the purer limestone, whence the French term it *chaux carbonatée lente*. It affords excellent lime for cements, but is not adapted to agricultural purposes, probably in consequence of the lime remaining so long caustic.

When an alkaline carbonate is poured into a solution of a salt of magnesia, a white gelatinous precipitate is formed, which is a hydrated carbonate of magnesia, or a combination of the hydrate and of the carbonate. The proportions of these two compounds vary according to the quantity of alkaline carbonate employed, the strength of the solutions, and the temperature. This product is made in large quantities in pharmaceutical chemistry, and is the *magnesia alba* of the pharmacopœia. Two kinds, identical in composition, are prepared, namely, the *light* and the *heavy*. For *heavy* magnesia, add one volume of a cold saturated solution of carbonate of soda to a boiling mixture of one volume of a saturated solution of sulphate of magnesia, and three volumes of water; boil until effervescence has ceased, constantly stirring with a spatula; then dilute with boiling water, set aside, pour off the supernatant liquor, and wash the precipitate with hot water on a linen cloth; afterwards dry it by heat in an iron pot. *Light* magnesia is prepared by employing dilute solutions of the sulphate of magnesia and carbonate of soda. If no heat be used, it is apt to be gritty.

A heavy granular magnesia is prepared by separately dissolving twelve parts of sulphate of magnesia, and thirteen parts of crystallized carbonate of soda, in as small a quantity of water as possible, mixing the hot solutions, and washing the precipitate. The light cubes of magnesia are prepared as follows:—A solution of one hundred parts of sulphate of magnesia in one hundred of water, is put into a vat heated by steam; a solution of one hundred and twenty-five parts of crystallized carbonate of soda is quickly stirred into it, and the temperature raised to 176° , to expel carbonic acid, which holds some of the magnesia in solution; the liquor is then decanted off the precipitate, and this is washed three times by subsidence, and decantation with lukewarm water, free from salts of lime. It is then transferred to linen strainers, and allowed to drip from twenty-four to forty-eight hours, and is transferred in a wet state to cubical boxes without bottoms, placed upon a table of plaster or porous stone, which quickly absorbs the water: after some time, the boxes are turned upside down, so as to present the upper side of the magnesia to the absorptive surface: the exsiccation is completed in warm rooms.—*Tomlinson*.

PEREIRA remarks that the *heavy* carbonate of magnesia is a granular substance, and contains no traces of the prismatic crystals observed in the light carbonate. When submitted to microscopic investigation, it is seen to consist of granules of various sizes; the larger ones are highly refractive, globular, and composed of concentric layers of a radiated structure. When examined by the polarising microscope, they are found to possess a doubly refracting structure; and, like the globules of carbonate of lime deposited from the urine of horses and bullocks, show the black cross. When

placed over a plate of selenite, and examined by polarised light, the quarters or spaces between the arms of the cross are colored: those next to each other show complementary tints—the alternate ones the same tints. Thus, if the first quarter be green, the third will be green also; but the second and fourth will be red.

The carbonate of magnesia of commerce is likewise obtained in various ways from bittern. It is also separated from magnesian limestone by a process adopted by Mr. PATTISON, which consists in calcining it at a dull red heat, by which only the magnesian carbonate is decomposed; the calcined stone is then diffused through water, and subjected to the action of carbonic acid, under pressure, by which the magnesia alone is dissolved, and is afterwards obtained by rapidly boiling down the solution. It is a beautiful white substance, very light, and without taste or smell. It dissolves in two thousand five hundred parts of cold, and in nine thousand parts of hot water, and is generally composed of—

	Centesimally.
Magnesia,	53.60
Carbonic acid,	41.73
Water,	4.67
	100.00

By passing a current of carbonic acid through a mixture of water and carbonate of magnesia, a clear solution is obtained, which, surcharged with carbonic acid, is a useful preparation that has been extensively advertised under the name of *soluble magnesia*, or *bicarbonate of magnesia*. This compound cannot be obtained in the solid or crystalline form, for the solution gives, by evaporation, oblique rhombic prisms of hydrated carbonate of magnesia, which on being put into cold water are decomposed, carbonate of magnesia being dissolved, and a subcarbonate deposited.—*Tomlinson*.

Citrate of Magnesia.—This is prepared by saturating a solution of citric acid with carbonate of magnesia. It is a white pulverulent insipid salt, very soft to the touch, heavier than magnesia, and when a slight excess of citric acid is present, is dissolved readily by water. Its composition is— 3 MgO , Ci , HO , or 3 MgO , $\text{C}_{12} \text{ H}_5 \text{ O}_{11}$, HO ; equivalent weight, 234.

It is a slight and agreeable aperient, and its superiority over other saline deposits consists in its being devoid of any disagreeable taste.

Tartrate of magnesia is obtained in a similar way to the preceding salt, substituting tartaric for the citric acid, and evaporating the solution to dryness at 212° . The resulting crystals consist of 2 MgO T , 8 HO , or 2 MgO , $\text{C}_8 \text{ H}_4 \text{ O}_{10}$ + 8 HO . Equivalent weight, 234. This salt has been used with success in painful chronic maladies of the spleen.

Sulphate of Magnesia.—This salt is now largely manufactured in Manchester, and is employed as a disinfectant, *et cetera*. Full particulars with regard to its use are given in Vol. I., page 565.

Steatite or Soap-stone.—This substance, remarks KNAPP, is known also under the more familiar names of Spanish or Venetian chalk, and is composed of silica,

magnesia, alumina, oxide of iron, oxide of manganese, and water. It is found in North America, Sala in Sweden, Cornwall, and China. It is employed in polishing articles made of serpentine, marble, sulphate of lime, and plate-glass; it is also sometimes used as a substitute for grease for the axles of carriages. It is further used for sketching in outline on silk, linen, and glass; as crayon; for painting on glass, and for removing stains in woollen and silk goods. It has also been added in some cases to the materials for porcelain, to improve the transparency, but it renders the mass much more brittle. The apparatus employed for the production of chlorine is occasionally manufactured from this material, as it resists the corrosive action of that remarkable gas.

Meerschäum.—Silicate of magnesia, under this name, is employed in manufacturing the celebrated tobacco-pipes; its composition is as follows:—

BRANDE states, that the salts of magnesia are mostly soluble in water, and bitter; they are all soluble in hydrochloric acid; their aqueous solutions are precipitated by potassa and soda, the precipitate being soluble in hydrochloric, nitric, and sulphuric acids, and in hydrochlorate, nitrate, and sulphate of ammonia. Ammonia only throws down part of the magnesia, and forms a double salt, and carbonates of potassa and soda only throw down part of the magnesia, except the solution be heated, when nearly the whole is precipitated. Chloride of ammonium redissolves the deposit, and when previously added to the magnesian solution, no precipitate ensues on adding the alkaline carbonates, unless the liquor be warmed. The bicarbonates of

ammonia, potassa, and soda, give no precipitate in magnesian solutions, except the liquor be boiled. Common phosphate of soda only precipitates concentrated magnesia solutions, but if ammonia or carbonate of ammonia be added, the magnesia is thrown down in the form of ammonio-magnesian phosphate. Moistened with nitrate of cobalt, and heated before the blow-pipe, *the magnesian salts give pale rose-colored compounds*: the tint is only distinct on cooling, and never very intense.

The separation of magnesia and lime is a problem of some importance in analytical chemistry, as they often exist together in the same mineral, especially in the varieties of magnesian limestone. PHILLIPS proposes the following process:—To the hydrochloric or nitric solution of lime and magnesia, add sulphate of ammonia in sufficient quantity; evaporate the mixture gradually to dryness, and then heat the residue to redness, till it ceases to lose weight, by the volatilization of the chloride of ammonium or nitrate of ammonia formed. Note the weight of the mixed salt, reduce it to powder, and wash it with a saturated solution of sulphate of lime till all the sulphate of magnesia appears to be dissolved; dry the sulphate of lime left, and by deducting its weight from that of the mixed sulphates, the quantity of magnesia dissolved will appear. Dissolve the two earths in hydrochloric acid in excess, and saturate the acid liquor by ammonia, then add oxalate of ammonia, and collect the precipitated oxalate of lime on a filter; the magnesia which is retained in the filtered liquor, may be thrown down by phosphate of soda in the form of ammonio-magnesian phosphate, or the solution may be evaporated to dryness, and the residue heated red-hot so as to leave magnesia. Evaporate the hydrochloric solution of the two earths to dryness, and expel the excess of acid from the residue, by heating in a platinum crucible: powdered chlorate of potassa is then added so long as the evolution of chlorine is perceived. On treating the residue with water, chloride of calcium and chloride of potassium are dissolved, and pure magnesia remains, which is separated upon a filter, washed, ignited, and weighed; the lime in the filtrate may be precipitated by oxalate of ammonia.

Separation of magnesia from the fixed alkalis.—Add subphosphate of ammonia to the solution, to throw down the magnesia as ammonia-phosphate, and filter; add acetate of lead to the filtrate, as long as it occasions any precipitate; filter again and supersaturate the clear liquor with sulphide of hydrogen; separate the sulphide of lead, and evaporate the solution to dryness. The residue, consisting of acetates, may be converted by hydrochloric acid into chlorides of potassium and sodium, which may be dissolved in water, and chloride of platinum will then throw down the potassium, which may be estimated from the weight of the potassio-chloride.

Quantitative Analysis.—This alkaline earth is almost invariably precipitated from an ammoniacal solution by phosphate of soda; it is collected and washed, and ignited so as to be weighed in the state of pyrophosphate. Every one hundred parts of ammonio-magnesian phosphate, dried at 60°, indicate 16·26 of magnesia:

every one hundred parts of its residue, after ignition, indicate 35·7 parts of magnesia.—*Brande*.

LIEBIG proposed another method to separate magnesia from potassa and soda. The bases are combined with sulphuric acid, the solution is rendered neutral, and is precipitated by a solution of sulphide of barium, which separates all the potassa and all the soda from the magnesia. The alkalies remain in the liquor in the state of sulphide of potassium, or of sodium, together with the excess of sulphide of barium employed. This liquor is decomposed by sulphuric acid, and the sulphate of baryta produced is collected on a filter; by evaporating the alkali, the sulphate of alkali is obtained. This alkaline product is then to be weighed, and from this weight the quantity of the alkali may be calculated. The best method of extracting the magnesia from the precipitate produced by the sulphide of barium—a precipitate which consists of magnesia mixed with sulphate of baryta—is to use an acid, and sulphuric acid in preference—to filter, in order to separate the sulphate of baryta produced, and the magnesia may be determined afterwards as a sulphate of magnesia.

The sulphide of barium employed for this method of analysis, must be crystallized and washed with cold water; such as it is obtained from the boiling of the product of the calcination of a mixture of sulphate of baryta and of charcoal.

Hydrate of baryta may be substituted for sulphide of barium with the same result.

The fixed alkalies may be more easily separated from magnesia when these bases are combined with nitric acid. The nitrates are to be calcined, which may be done in a platinum crucible, by adding a little dry carbonate of ammonia to the mass, after exposure to the first impression of the heat, and then moderately urging the fire. When the calcining is finished, the residuum is treated with water, which dissolves the alkalies in the state of carbonates, and leaves the magnesia behind.

When the fixed alkalies and magnesia are contained in a solution in the state of metallic chlorides, the method formerly in use for separating them consisted in evaporating the liquor to dryness, and igniting the dry residuum; the water of crystallization of the chloride of magnesium converted the latter into magnesia, with disengagement of hydrochloric acid; after which the chloride of the alkalisable metal was separated from the magnesia by washing with water.

This method may often be employed with advantage in qualitative analysis, but in quantitative the results obtained by it *are quite inaccurate*; for even after a protracted ignition there remains a great quantity of undecomposed chloride of magnesium, which dissolves in the water with the alkaline chloride. If strong alcohol is employed instead of water for washing the strongly ignited mass, it does not give a better result, for alcohol dissolves the undecomposed chloride of magnesium, just as water does, and leaves the magnesia thus produced undissolved.

Yet if, after having put the mixture of chloride of magnesium and of the alkalisable metal in a small platinum crucible, it is exposed to a red heat for a long time over a gas lamp, placing at the end a small piece of carbonate of ammonia upon the mass, and then

igniting strongly, nearly the whole of the chloride of magnesium may be converted into magnesia; but the calcination with the ammoniacal salt *must be repeated several times*, and the salt must be moistened with a few drops of water before calcining. The operation is known to be at an end when the weight of the saline mass remains constant after ignition. It is then treated by water, which dissolves the alkaline chloride, and along with it a trace of magnesia. The magnesia which remains insoluble is ignited and weighed. It is completely soluble in nitric acid, and when tested by nitrate of silver hardly shows a trace of chlorine. During the ignition of the mass it is advisable to put the cover on the crucible, in order to keep in the vapor of carbonate of ammonia as long as possible, and to prevent, at the same time, the access of air.

When the operation is performed on a few grammes of a mixture of chloride of magnesium, and of the chloride of an alkalisable metal, the treatment with carbonate of ammonia and water must be repeated at least eight times. The unavoidable loss of chlorine, which takes place when this method is resorted to, does not amount to one per cent. Of course, the chlorides which the operator purposes to separate *must contain no trace of sulphuric acid*.

In order to avoid the tedious operations which are necessary for an actual separation of magnesia, potassa, and soda, particularly when they do not exist together in the state of pure chlorides, Dr. LIST endeavored to determine them conjointly by an indirect method. The following is the process he found practically applicable in the most complicated cases, such as is presented by the analysis of a silicate decomposed by hydrofluoric acid:—

The filtrate obtained after precipitation of all other bases, is evaporated to dryness in a water-bath, and the residue of sulphates and chloride of ammonium cautiously ignited in a platinum crucible to expel the ammoniacal salt. The perfect safety of this operation from all loss may be insured by employing a crucible lid with an interior convex surface. As it is an indispensable condition for the success of the subsequent result that sulphuric should be the only acid present, the ignited saline mass is moistened with a little sulphuric acid, and again evaporated to dryness. To change the acid salts into neutral, a piece of carbonate of ammonia is then placed in the crucible, and this again heated until the bottom becomes feebly red. This operation is repeated until the weight remains constant. This chemist ascertained that the pure sulphate of magnesia loses no sulphuric acid. The contents of the crucible are now dissolved in water, and the sulphuric acid in the solution determined by chloride of barium; when the excess of baryta has been removed by sulphuric acid, the magnesia is precipitated by ammonia and phosphate of soda, and determined in the usual manner.

Dr. LIST proved the applicability of this method by operating upon a known mixture of sulphates of potassa, soda, and magnesia. After having convinced himself of the purity of the individual salts, by a determination of their sulphuric acid, he mixed the three, and, analysing the mixture, found the required quantities within 0·001 per cent.

The sources of this minute error are certainly of much less importance than those which are found to exist in the process by direct separation, especially as the determination of sulphuric acid and magnesia is one of those operations which can be effected with the greatest accuracy.

MANGANESE.—*Manganèse*, French; *Mangan*, German; *Manganum*, Latin.—The black mineral known in commerce by the name of manganese—*braunstein*, German—has long been employed to counteract the green tint of glass. It was formerly called *magnesia nigra*, from its resemblance to the magnetic oxide of iron, or loadstone. A mine of this mineral was discovered in England by BOYLE. Some experiments were made upon it by GLAUBER in 1656, and by WAIZ in 1705; but chemists do not appear to have directed particular attention to it until a later period. Mineralogists agreed in classing it among the ferruginous ores until POTR, in 1740, showed that it often contains mere traces of iron; after which, on the supposition that it consisted chiefly of a peculiar earth, a separate place was assigned to it in treatises on mineralogy. This hypothesis was, in the year 1774, distinctly proved to be correct, by the elaborate researches of SCHEELE and BERGMAN. GAHN subsequently showed that this earthy base contained a metal, not hitherto isolated, upon which he bestowed the appellation of *magnesium*. As, however, this term was afterwards employed to distinguish the metallic base of magnesia, it was superseded by the designation now in use. The metal manganese, owing to its powerful attraction for oxygen, does not occur in a free state in the earth's crust; but its mineral oxides are abundant, and are extensively employed in the arts, chiefly in the manufacture of glass and pottery, and in the preparation of chlorine for the production of bleaching-powder.

PREPARATION.—From the difficulty of its isolation, metallic manganese has not been rendered available for any useful purpose. The processes for its reduction are generally conducted on a small scale, in the laboratory. Like iron and cobalt, it is very difficult to be obtained in a state of absolute purity. It is necessary, in the first place, to procure a pure oxide of manganese, which may be effected by any of the following processes:—The common black oxide of manganese of commerce is digested for some time with dilute hydrochloric acid, washed, in order to free it from carbonate of lime, and then heated with strong hydrochloric acid. During the solution of the mineral, chlorine gas is abundantly disengaged, and, when the action is complete, the solution contains chloride of manganese and sesquichloride of iron. The liquid, after filtration, is evaporated to dryness in a porcelain basin, and the dry residue is strongly heated, with constant stirring, until it assumes an ash-grey hue, and no longer evolves acid fumes. By this treatment the chloride of iron is in part volatilized, and in part converted into sesquioxide of iron and hydrochloric acid. The residue is now digested with water, the solution filtered, and carbonate of soda, in slight excess, added to the liquid. The precipitated carbonate, after washing and drying, is ignited, when it furnishes a pure oxide; or the solution in hydrochloric acid is diluted with

water, and treated with repeated quantities of carbonate of soda, with continued digestion and stirring, until the liquid, rendered clear by subsidence or filtration, gives a pure white precipitate with a further quantity of carbonate of soda, showing that all the oxide of iron has been precipitated. This having been attained, the whole solution is freed by filtration from the precipitate, and the clear liquid precipitated by carbonate of soda in excess.

FARADAY recommends the following process for the preparation of pure protochloride of manganese:—Finely-powdered and strongly-calined black oxide, previously cleansed from carbonate of lime, is ignited with half its weight of chloride of ammonium, beginning with a moderate heat, and gradually raising the temperature to low redness. The chloride of manganese formed is dissolved out and the solution filtered. The pure oxide of manganese, prepared by the process already indicated, is moistened with oil and heated to redness several times, then made into a thick paste with oil, introduced into a charcoal-lined crucible, covered with charcoal powder, and a lid luted on the mouth of the crucible, which is afterwards exposed, for two or three hours, to the strongest heat of a smith's forge or a powerful blast furnace. SEFSTROM's apparatus, represented in Fig. 355 is commonly employed for the reduction. In a cylindrical iron case, A, is placed a second cylinder, B, lined with

Fig. 355.

fire-brick. The crucible is arranged as represented in the drawing, and surrounded with glowing charcoal or coke. The blast is admitted at F into the space which intervenes between the two cylinders, from which, after becoming considerably heated, it is forced into the fire-chamber through a series of openings, D D. The metal collects in the form of a button at the bottom of the crucible.

PROPERTIES.—Metallic manganese, as thus obtained, presents a greyish-white color without much lustre, and a fine granular texture. It is rather soft and brittle, and is readily split or broken. Its specific gravity is stated by JOHN to be 8.013. Its equivalent is 27.6. When pure it is not attracted by the magnet. It is exceedingly difficult of fusion, requiring for liquefaction the most intense heat of a wind furnace. The manganese prepared by the process described is always contaminated with carbon and silicium, and resembles,

therefore, common pig or cast iron. On subjecting the metal to fusion with borax, the carbon is separated, and the regulus becomes more fusible; but it is probable that the product, in this case, contains boron or sodium. Manganese readily tarnishes by exposure to the air—hence, like potassium, it must be kept under naphtha. When heated to redness in open vessels, it absorbs oxygen with rapidity. It decomposes water slowly at common temperatures, with disengagement of hydrogen gas; but at a red heat oxidation is very rapid. It also dissolves readily in dilute acids, with escape of hydrogen. By fusion at a high temperature, manganese may be alloyed with various other metals. A compound of about four equivalents of manganese and one equivalent of iron, was produced in considerable quantity by BUTTRAY, in a furnace employed for fusing cast-steel. This alloy became only slightly tarnished when freely exposed to the air, and did not affect the magnetic needle. When manganese is combined by fusion with six or seven *per cent.* of silicium, a regulus results which possesses the appearance of the ordinary metal, but differs much from it in its chemical characteristics; it does not oxidise, even at a red heat, and withstands the action of nitro-hydrochloric acid—*Sefström*.

BERZELIUS expressed the opinion, that the presence of the small proportion of silicium is not suffi-

cient to account for this total change of properties, and that there must exist in the compound or alloy, an allotropic modification of the metal, the alteration being effected or induced by the presence of the silicium at a temperature at which it would not occur with manganese alone.

C. BRUNNER has recently prepared metallic manganese, by acting upon the fluoride with half its weight of sodium, the process being similar to that employed for the reduction of aluminium. Manganese thus obtained possesses properties essentially different from those usually attributed to this metal. Its color is like that of some cast-iron; it is brittle and very hard, not yielding to a steel file, but, on the contrary, scratching the best-tempered steel. It is capable of the most perfect polish. It is not altered even in moist air at the ordinary temperature. When heated, it acquires nearly the same colors as steel, passing afterwards to brown, by covering itself with a layer of oxide. The specific gravity of different specimens varied from 7.138 to 7.206. It is not attracted by the magnet, even when in powder, and has no influence on the magnetic needle. Acids attack it violently, even in the cold.

OXIDES.—Manganese forms at least five distinct compounds with oxygen, besides several compound oxides. The composition of these oxides is exhibited in the following table:—

Protoxide, or manganous oxide,.....	Mn O.
Sesquioxide, or manganic oxide,.....	Mn ₂ O ₃ .
Binoxide, or peroxide—black oxide,.....	Mn O ₂ .
Manganoso-manganic oxide—red oxide,.....	Mn ₃ O ₄ , or Mn O, Mn ₂ O ₃ .
Varvicite,.....	Mn ₄ O ₇ , or Mn ₂ O ₃ , 2 Mn O ₂ .
Manganic acid,.....	Mn O ₃ .
Permanganic acid,.....	Mn ₂ O ₇ .

Of these the first only possesses marked basic properties; the sesquioxide is a very feeble base; and the two compounds at the bottom of the list are, as their names indicate, acids. The protoxide is readily obtained by heating the oxalate in a covered crucible or in a glass tube closed at one end. When a caustic alkali is added to a solution of chloride or sulphate of manganese, the hydrated oxide falls as a flocculent white precipitate, which rapidly acquires a dark tint on exposure to the air. Binoxide of manganese may be prepared by passing chlorine gas through a solution of the acetate. Sesquioxide of manganese is produced when the binoxide is kept for a considerable time at a moderate red heat: it also occurs in nature as *braunite* and *manganite*. The red or manganoso-manganic oxide is always produced when any of the higher oxides is exposed to a white heat, either in closed or open vessels, or when hydrated protoxide is exposed to the air. It is the most permanent of all the oxides of manganese; it is not affected by exposure to any temperature, while all the other oxides readily pass into it, under the influence of heat. When finely powdered it is brownish-red while cold, and nearly black while warm. When fused with borax or glass, it communicates to these bodies a beautiful violet or amethyst tint, a character by which manganese may readily be detected before the blowpipe. Many colored minerals—for example, the amethyst—owe their tint to the presence of this oxide. Manganate of potassa is readily produced by

fusing binoxide with carbonate or hydrate of potassa, with or without the addition of chlorate. The compound has a fine green color. Upon the ready formation and great coloring power of manganic acid, E. DAVY has founded an elegant method for the detection of manganese. The substance is heated on silver foil, with a drop of a strong solution of caustic potassa, and the dry residue is gently ignited, when it will exhibit, if manganese be present in appreciable quantity, a very distinct green color. When compounds of manganese are heated before the blowpipe with carbonate of soda, on a loop of platinum wire, a green bead is obtained, manganate of soda being formed. Manganate of potassa has received the name of *chameleon mineral*, from the circumstance that the dark-green solution obtained by digesting it in a small quantity of cold water, assumes various shades of color on being diluted, the ultimate result being a liquid, having a fine carmine-red tint. The change of tint, which is induced more readily by the addition of an acid, is owing to the resolution of the manganic into permanganic acid, which remains in solution, and binoxide of manganese, which falls as a precipitate.

CRUM's test for manganese depends upon the formation of permanganic acid. The compound under examination is dissolved in a little nitric acid, and binoxide of lead added, when, the fine red tint of per-

manganic acid will be communicated to the liquid. Solution of permanganate of potassa is much employed in the German and French laboratories as an oxidising agent: in this country the bichromate is more generally used. The solution is best prepared by the method recommended by GREGORY. Four parts of finely-pulverized binoxide of manganese, and three and a half parts of chlorate of potassa, are intimately mixed together, and added to five parts of hydrate of potassa dissolved in a small quantity of water. The mixture is evaporated, and the residue completely dried, pulverized, and exposed to a low red heat, in a platinum crucible. The agglutinated mass is again powdered and added to a considerable quantity of boiling water, and the solution allowed to settle. When clear it is decanted, and is ready for use. It is quite permanent when preserved in well-stoppered bottles.

All the higher oxides of manganese are reduced to the condition of protocompounds by the action of warm sulphuric or hydrochloric acid, with the elimination of oxygen or chlorine, as the case may be. The following equations represent the action of hydrochloric acid upon the binoxide, the sesquioxide, and the red oxide of manganese:—

Protoxide of manganese is a powerful base of the magnesian class. Its salts are sometimes quite colorless; but they frequently possess a pink shade, probably from the presence of traces of permanganic acid, or oxide of cobalt. The soluble salts are nearly neutral, and when dissolved exhibit the following reactions:—

Caustic Potassa,.....	} A white precipitate of hydrated protoxide, which becomes brown by the absorption of oxygen.
Ammonia,.....	
Alkaline carbonates and bicarbonates,.....	} White precipitate.
Ferrocyanide of potassium,....	
Sulphide of hydrogen,.....	} Do.
Sulphide of ammonium,.....	
	} No effect in acid solutions.
	} A flesh-colored precipitate.

For the detection of minute quantities of manganese,

especially when mixed with other metals, CRUM's test, already detailed, is probably the most delicate.

ORES.—The compounds of manganese which occur native are numerous, but as those only are of importance in the arts, which consist solely or chiefly of one of the higher oxides, the minerals which come under consideration in this place are comparatively few in number.

Pyrolusite is the name applied to the native binoxide in its anhydrous and crystallized state. It is chiefly this variety that is employed by the glass-makers, while *wad* and other less pure ores are consumed in the elimination of chlorine from hydrochloric acid or chloride of sodium. The crystalline form of pyrolusite is the rhombic prism, and it generally occurs in the form of minute crystals grouped together, and radiating from a common centre. It has the same form as *manganite*, which consists of hydrated sesquioxide, and appears to be formed from that mineral by absorption of oxygen and loss of water, some masses of crystals having been observed to consist of pyrolusite externally and manganite internally. Pyrolusite has an iron-black or dark steel-grey color, and a metallic lustre. It is not very hard; its specific gravity is 4·7 to 4·97. It frequently contains *manganite*, *psilomelane*, sesquioxide of iron, alumina, silica, baryta, carbonate and sulphate of lime, and occasionally, according to PHILLIPS, traces of chloride of calcium. The following analyses of specimens of pyrolusite are by TURNER:—

	Elgersburg.	Ihlefeld.

This valuable ore is extensively worked in Ilmenau, Elgersburg, and various other districts in Thuringia; and the mines at Vorderschrensdorf, in Moravia, yield annually many hundred tons. It has also been found in several localities in America and elsewhere.

Wad is the native hydrated binoxide. It is this ore that is commonly employed in the preparation of chlorine. It is tolerably abundant, and is found in England, Ireland, Sweden, Germany, and America; it appears generally in the form of brownish-black masses, or loosely agglomerated brown scales. Some varieties are hard and compact, and difficult to pulverise; others are comparatively soft and ochrey. *Wad* consists essentially of hydrated binoxide of manganese, $\text{Mn O}_2 \cdot \text{HO}$, but it is always more or less mixed up with manganic or manganoso-manganic oxide, and generally with variable quantities of sesquioxide of iron, clay, quartz, baryta, carbonate of lime, *et cetera*. Some specimens contain much oxide of cobalt, and a few contain oxide of copper. Analyses of specimens of *wad* from various localities, and of other ores of manganese capable of being applied to economic purposes, are exhibited in the preceding table. The last column of the table shows the amount of pure binoxide corresponding with the quantity of chlorine yielded by one hundred parts of the ore.

Psilomelane is one of the most generally diffused ores of manganese. It is compact and fibrous; specific gravity 4 to 4.328; rather hard. It has a dark steel-grey color, and submetallic lustre; it generally occurs in botryoidal masses.

Braunite is met with in octohedral crystals, and also massive; it is commonly nearly pure sesquioxide of manganese. *Manganite*, or grey manganese ore, is the hydrated sesquioxide, $\text{Mn}_2 \text{O}_3 \cdot \text{HO}$, and is generally very pure, and, therefore, well adapted for the manufacture of glass. It occurs in rhomboidal prisms, and also in columnar and granular masses. It is moderately hard; specific gravity 4.3 to 4.4; color between iron-black and steel-grey, with a submetallic lustre. It is found at Ithfeld in the Hartz, in Aberdeenshire, Bohemia, Saxony, and other localities.

USES.—The most important applications of manganese ore in the arts, are the production of chlorine and the decoloring of glass. Although, in the manufacture of glass, the purest materials are employed, yet traces of iron compounds are invariably present in one or more of the materials, giving to the product a very faint but distinct green, olive, or yellow tint, according to the state of oxidation of the metal. The cautious addition of black oxide of manganese destroys or conceals the objectionable tint. Its action was formerly supposed to be merely the oxidation of the green protoxide of iron to the faint yellow sesquioxide; but LIEBIG has suggested that the effect is not chemical but optical, and that the amethyst color communicated by the red oxide of manganese counteracts the yellow or greenish-yellow tint of the oxide of iron. This is probably the correct explanation of the action, since other oxidising agents, red oxide of lead for example, do not produce the desired effect. Chemists employ the binoxide of manganese for the preparation of oxygen and chlorine gases, and it is employed, in conjunction with dilute sulphuric acid, as an oxidising agent in organic chemistry.

Bin oxide of manganese has been employed for increasing the siccative quality of linseed oil; and the artificial bin oxide, mixed with the same oil, has been

recommended as a black paint, which may be used with advantage for the manufacture of printers' ink.

Of the numerous combinations of manganese with the halogens, and of the oxides with acids, the acetate, protochloride, and the sulphate of the protoxide are the only compounds which are manufactured on the large scale or applied to economic purposes, and are, consequently, sufficiently important to claim consideration in a work on technology.

Acetate of Manganese.—A full description of this salt is given in Vol. I., page 46.

Chloride of Manganese.—A solution of this compound in a state of purity is most readily obtained by the method recommended by FARADAY, already detailed, or by digesting a solution of purified black oxide of manganese in hot and strong hydrochloric acid, with carbonate of manganese, until all the sesquioxide of iron is displaced and thrown down. When the solution is highly concentrated by evaporation, it yields crystals of the hydrated salt, $\text{Mn Cl} \cdot 4 \text{ HO}$. These crystals are highly deliquescent, and they dissolve in two-thirds of their weight of water at 60°, and in a much smaller quantity at a higher temperature. The salt may be rendered anhydrous by the application of the heat of a spirit flame, while inclosed in a glass tube through which a current of dry hydrochloric acid gas is made to pass. It is a rose-colored crystalline mass.

Chloride of manganese is a refuse or waste product in chemical factories where chlorine is prepared from manganese and hydrochloric acid. It has been employed in the purification of coal gas. It may be used in dyeing for the production of *manganese-brown*, but the sulphate is generally employed for this purpose. A crude solution of chloride of manganese, neutral and free from iron, may be prepared by digesting the refuse menstruum already referred to with powdered chalk, which decomposes the sesquichloride of iron, but does not affect the manganese salt.

Sulphate of manganese is obtained in transparent, slightly rose-colored crystals, by dissolving the pure carbonate in dilute sulphuric acid, and concentrating by spontaneous evaporation. The crystals have the form of sulphate of copper, and a similar composition, $\text{Mn O} \cdot \text{SO}_3 + 5 \text{ HO}$; but by evaporation and crystallization at various temperatures, crystals with greater and less proportions of water may be obtained. The crystals are remarkably soluble in water.

This salt is prepared on a considerable scale for the use of the dyer and calico-printer. The mode of preparation generally adopted is as follows:—Black oxide of manganese is ignited with a small quantity of charcoal powder, in order to reduce it to the state of protoxide. This product being now treated with moderately dilute sulphuric acid, a crude sulphate is obtained containing a considerable proportion of sulphate of iron, to get rid of which the solution is boiled down to dryness, and the residue ignited or roasted. The mass is digested with water, when the manganese salt dissolves, while the iron remains insoluble as a basic sesquisulphate. The salt is obtained from the solution by evaporation. Another mode of preparation is, to ignite a mixture of black oxide of manganese and sulphate of iron, then to digest in water, and evaporate the

solution. *Manganese brown*, or *bronze*, is produced by immersing the fabric in a solution of sulphate of manganese, and then in one of dilute caustic alkali to precipitate the protoxide, which is raised to a higher state of oxidation either by simple exposure to the air, or, more rapidly, by transmitting it through a solution of bleaching powder.

PROCESSES FOR THE RECOVERY OF MANGANESE.—It has been customary for manufacturers who eliminate chlorine on the large scale, to throw away the chloride of manganese that results. To prevent this enormous loss of valuable material, various methods have been proposed and patented for recovering the manganese, or reconverting the chloride into the binoxide or sesquioxide. It is well known that the protoxide of manganese is readily converted by the oxygen of the air into the sesquioxide by gentle ustulation; and it was mentioned long ago by FORCHHAMMER, that carbonate of manganese, when heated in an open vessel to 500°, is converted for the most part into binoxide, an observation which does not seem, until very lately, to have attracted that degree of attention which its importance merits. The two most recent patent processes for the recovery of manganese, are those of BALMAIN and DUNLOP.

The invention of W. H. BALMAIN, whose patent is dated 31st March, 1855, is a method for attaining an economical recovery of the oxide of manganese by carrying on the process in conjunction with the manufacture of chloride of ammonium from the ammoniacal water formed in making coal gas. The mode of proceeding is as follows:—Into a convenient tank or pan, a quantity of the ammoniacal gas water is run, and to it is added the solution of manganese produced in the manufacture of chlorine, until a further addition of the solution causes no precipitation or thickening, or until the supernatant clear liquor does not effervesce with acid. The mixture having been allowed to stand for some time, the clear liquor is drawn off and evaporated for the purpose of crystallizing out the chloride of ammonium which it holds in solution. Water is then run upon the sediment, which is agitated, and is then allowed to subside. The supernatant clear liquor is then drawn off and treated in the same manner as the first liquor, in order to extract from it the remaining chloride of ammonium. The sediment is now removed to a bed of sand or cinders, and allowed to lose as much water as will mechanically run off by drainage. It is then placed upon a hearth or ordinary furnace-bed, and heated to redness, either by means of an open fire or by flues above and below, until it ceases to burn like tinder, and has assumed a black color; by which time it will have been converted into an oxide of manganese, fit for use, in the manufacture of chlorine, or for any other purpose to which it might have been applied in its original form.

When the manganese is to be used for producing chlorine, it is advisable to mix lime with the sediment before drainage, or as soon as it dries upon the hearth, and thus resolve it more or less into manganate of lime, which increases its power of eliminating chlorine.

When the gas water to be operated upon is in a

town at a distance from the spot where the solution of manganese is produced, or when the recovered manganese is to be used in the manufacture of glass, the liquid chloride of manganese is boiled down, and heated in a furnace to such a temperature as will render oxide of iron insoluble; in which state it is carried to the neighborhood where the gas water is produced, and being redissolved in water, is mixed and treated as described in the first instance.

The oxide of manganese having been used a second time, may be again recovered a third and a fourth time; and if no lime or alkali-waste has been used in neutralizing the excess of acid, it may be recovered an indefinite number of times.

The patent granted to CHARLES TENNANT DUNLOP, and dated 31st May, 1855, relates to the employment of the residuum obtained in the manufacture of chlorine, which residuum ordinarily consists of chloride of manganese, in the preparation of an artificial oxide of manganese, that is well suited for the manufacture or production of chlorine. The special process preferred by the patentee in carrying out his invention, is the transformation of the chloride of manganese into a carbonate of that metal by the agency of any of the means already well known to chemists, and then subjecting the carbonate, thus prepared, to the action of heat in contact with atmospheric air. Whatever impurity the chloride of manganese may contain—as chloride of iron for instance—is first separated either by calcination, or by the agency of a suitable precipitant. Practical working has decided that the carbonate of manganese, thus treated, yields an oxide of manganese of a richness equivalent to about eighty per cent. of pure sesquioxide.

The carbonate of manganese may be obtained by precipitation from the chloride, by the agency of carbonate of ammonia. The chloride of ammonium resulting from this treatment, may either be sold or employed as such, or it may be converted into a carbonate in the usual way, and then again employed for the precipitation of fresh chloride of manganese. Hydrate of lime is also employed in the production of carbonate of manganese from these residual matters; the hydrated oxide of manganese being subsequently transformed into carbonate by the transmission through it of carbonic acid.

By another process, carbonate of manganese is obtained by passing carbonic acid through the solution of chloride of manganese, which has been previously mixed with a quantity of carbonate of lime. The carbonate of lime, under the influence of the carbonic acid, decomposes the chloride of manganese into carbonate, from which the oxide of manganese can be obtained, as well as chloride of calcium, which remains in solution. The production of oxide of manganese, suitable for the preparation of chlorine, has often been attempted by following the process of precipitating the manganese as an oxide, and then bringing it to a higher state of oxidation by heating it in contact with atmospheric air, as well as by other means. But the essential feature of this invention is, the production of oxide of manganese from the residuum of the chlorine manufacture, by first manufacturing or producing the carbonate of manga-

nese, and then heating this carbonate in contact with atmospheric air. DUNLOP's process has been most extensively and successfully carried out by the Messrs. TENNANT of the St. Rollox Chemical Works, Glasgow. The carbonate is obtained in this establishment by heating in an iron boiler, under pressure, chalk and the refuse chloride of manganese, from which any iron which it may contain has been previously separated by the action of chalk in the cold. The carbonate of manganese thus procured is freed from the chloride of calcium in vats, collected, and then exsiccated in a chamber on a series of iron trays, in such a gradual manner as to expel the carbonic acid, and by elevating the temperature in a current of air, to obtain the black oxide.

QUANTITATIVE ESTIMATION.—Manganese is weighed almost invariably as the red oxide Mn_2O_3 , 114.8 parts of which are equivalent to 82.8 of metallic manganese, 106.8 of protoxide, and 130.8 of binoxide. When no other base is present, or only the alkalis, the moderately dilute solution is heated to boiling, and the manganese is thrown down as carbonate by the addition of carbonate of soda in excess. The precipitate is collected on a filter, washed with boiling water, dried and ignited over a powerful lamp or in a furnace, until the weight ceases to vary. The residue in the crucible is pure red oxide. If the liquid contains ammoniacal salts, it must be boiled with carbonate of soda in excess until the odor of the volatile alkali is no longer perceptible.

When any of the metals precipitable by sulphide of hydrogen are contained in the liquid, it must be rendered acid by the addition of hydrochloric acid, and treated with this agent, in order to remove them. Sesquioxide of iron is most readily separated by the addition of succinate of ammonia to the nearly neutral liquid. Manganese may be separated from the alkalis, earths, and the oxides of iron, nickel, and zinc, by the ingenious method of SCHIEL. The acid menstruum is nearly neutralized with carbonate of soda, acetate of soda added, and chlorine gas passed through the liquid to saturation. The manganese is completely deposited as hydrated binoxide, which may be converted into red oxide by ignition; the other bases remain in solution. The absolute separation of manganese and cobalt is attended with considerable difficulty; but the following simple method gives results which are sufficiently accurate for all technical purposes:—The two metals are precipitated by sulphide of ammonium and excess of acetic acid then added, when the sulphide of manganese dissolves, and the sulphide of cobalt remains intact.

The separation of manganese from nickel is given under the latter metal. Having obtained the sulphide of manganese by the process mixed with sulphide of zinc, it will be well to give here the mode of obtaining the manganese *per se*. Dissolve the sulphide in hydrochloric acid, then nearly neutralize with carbonate of soda, add acetate of soda, and next conduct chlorine gas into the mixture. The manganese salt is hereby decomposed, and the whole of the manganese separates as binoxide. The zinc remains in solution.

For the valuation and testing of manganese ores, the

reader is referred to the article BLEACHING POWDER, Vol. I., page 329.

Physiological Effects.—The effects of manganese upon the system are imperfectly known. KAPP regards it as a permanent stimulant, and says it promotes the appetite and digestion. VOGT places it among the tonics, and considers it to be intermediate between iron and lead; but his views are altogether theoretical, as he does not seem to have prescribed it. Dr. COUPER has described several cases of disease which took place among the men engaged in grinding it at the chemical works of Messrs. TENNANT and Company, in Glasgow; from these, it appears that, when slowly introduced into the system, it produces paralysis of the motor nerves. The disease commences with symptoms of the paraplegia. It differs from the paralysis of lead in not causing *colica pectorum*, or constipation; and from mercury, in first affecting the lower extremities, and in not exciting tumors of the afflicted part.

Manganese is rarely used in medicine; it appears to have been employed in the last century in the treatment of inflammatory fevers. GRILLE long since observed that the workmen in the manganese mines at Maçon were not subject to the itch; and that others who became affected with this disease, were cured by working in the mines. This led him, as well as MORELOT and others, to employ it in cutaneous maladies. KAPP administered it, as well as the salts of manganese, both internally and externally in various forms of syphilis; he used it with benefit in herpes, scabies, and the scorbutic diathesis. BRERA gave it in chlorosis, scorbutus, hypochondriasis, hysteria, *et cetera*. OTTO administered it in cachectic complaints, with favourable results. ODIER employed it in cardialgia. It has been applied as an absorbent in the treatment of old ulcers, as a depilatory, and as a remedy for skin diseases, especially itch and porrigo. KUGLER gave it with benefit in scrofula.

Manganic Acid.—HUNEFELD gave to a rabbit nearly two drachms of manganic acid in three days, in doses of ten or fifteen grains. The only obvious effect was increased secretion of urine. The animal being killed, the peritoneum and external coat of the colon were found of a greenish color—protoxide of manganese is of a pale grass-green color—the muscles were readily lacerated and livid, the liver was inflamed, the bile increased.—*Pereira*.

STATISTICS.—For all purposes, about twenty-five thousand tons of manganese are used annually; and of this quantity, from seventeen to eighteen thousand are employed for the manufacture of bleaching powder. The largest makers of the latter article are the TENNANTS of Glasgow, and MUSPRATTS of Liverpool, and Flint, North Wales.

MANURE.—*Engrais*, French; *Dünger*, German. The term, *manure*, is applied to all those substances which render soils more fertile. Manures produce their effects by contributing directly to the nutriment of plants, by improving the texture of soils, or by acting as chemical agents on the inert matters of the soil, by which they are transformed into a state fit for the use of plants.

Manures consist of vegetal and animal substances,

and of their products of decomposition, or of earthy, saline, and other bodies derived from minerals; consequently, they have generally been classed into vegetal and animal manures, mineral and mixed manures.

The history of manures cannot date so far back as the origin of agriculture, which was coeval with the foundation of society itself. In the earlier periods of the world, when the face of the ground was but thinly inhabited, and a virgin soil exhibited abundant fertility, the wants of man were readily supplied. With ample choice of ground at his command, he had only to remove to another spot, when land already under cultivation for some time no longer yielded the same increase. The fact of diminished productiveness, by prolonged cultivation, was no doubt early observed; but the reason of this did not probably give rise to much speculation, so long as the remedy was at hand in the fresh soil around. But as population increased, and the habits of men became less nomadic, the necessity of restoring to the exhausted soil its fertility, would become a question of serious consideration. The mode of doing this in the simplest way, would suggest itself by the observation of what passed around them. The refuse materials ejected from their habitations, the ordure of man and animals, the decaying carcasses of the latter, allowed to accumulate and rot on the surface of the ground, gave rise to a luxuriant vegetation on these spots, far surpassing that of the adjacent soil. The repeated observation of such facts cannot fail to have arrested attention, and to have led, on reflection, to connect cause and effect. It was thus early seen, that organic structures in a state of *eremacausis*, the filth from crowded habitations, and other matters which are offensive to the organs, when allowed to decay on exposure, were intended by nature to be buried under ground, and thus to effect at once the removal of pollution from the air that was breathed, and to restore the lost fertility of the soil. Hence the earliest form of manure, and that which has remained unchanged through succeeding ages, and at the present day still forms the standard of comparison for other manures, was a mixture of thecrement and urine of animals with other decaying animal and vegetal matter. In the writings of the Greeks and Romans are found many notices of the attention they paid to agriculture and manures.

COLUMELLA, who flourished during the early part of the first century of the christian era, wrote a great work, divided into twelve books, on agriculture. In the second of these he speaks of the breaking up and preparation of the ground, and gives an account of the different kinds of grain, pulse, and artificial grasses, with the tillage appropriate for each. He gives directions for carefully collecting the excrement of cattle, for littering them with straw, which was to be removed when soiled to the dunghill; and also advises the collection of all kinds of ashes, and the burning of weeds, shrubs, trees, and stubble, in fields; and the application of the incinerated matter as manure. The writings of this and other authors prove, that the ancients not only paid attention to the management of farmyard manure, but that they were well acquainted with the mode of preparing artificial and all ordinary composts. COLU-

MELLA says he is not ignorant that there are some farms in the country in which neither the dung of cattle nor of birds is to be obtained. However, he is a slothful husbandman who has no manure. He may, states the same authority, collect any kind of leaves, the cuttings of briars, and rakings of highways; he may cut ferns, and mix these with the cleanings of his courtyard; he may dig a hollow place such as was directed for the dunghill, and throw into it ashes, the dirt of the kennels, all kinds of straw, and everything that is swept from the house. Indeed, the various processes now followed by agriculturists to render the soil fertile, were known by the Romans. They incorporated light with heavy soils, and rendered them more porous; and although unacquainted with the theory of the operation, they may be said to have originated the principle of the modern process of subsoil-ploughing; for in some districts it was the custom every fifth or seventh year to dig as deep as the rain penetrated, and turn up the bottom of the mould, by which the corn-fields were said to be renewed, the particles of earth proper to the nourishment of the plants being supplied, to be carried downwards along with the rain. The practice of economising and employing farmyard manure and composts in general, may be said to have been transmitted from the Romans, with little change, to the beginning of the present century, varied only by the use and incorporation into composts of such articles as particular districts afforded. Thus chalk was employed in some places as a great adjunct to farmyard manure for turnips and all kinds of grain; in others, marl superseded lime; and along the sea-coasts, calcareous sea-sand, and seaweeds, were in high repute. In other districts, where manufactures were established, the refuse materials, such as soap-waste, under the name of soap-ash, woollen rags, *et cetera*, were in common use. Later still, animal matters, such as fish and bone, and other dressings, were in demand.

Although by the foregoing one sees what knowledge even the Romans possessed of manures, still they were far behind the Chinese in their system of agriculture. The basis of their mode is, as so often reiterated by LIEBIG, *to return to the soil every ingredient that has been removed by a crop*. The result has been, that instead of the land becoming impoverished, it has augmented in fertility with a continually increasing population, since the time of ABRAHAM or of the Egyptian Pyramids. All those means, says LIEBIG, which the German agriculturist considers perfectly indispensable for the increase of his produce, are not only quite unnecessary for the Chinese, *but without them* he produces crops more than double those of his Teutonic brother. No doubt other conditions exist in China different to Germany; some of them are Buddhists, and eat no meat, while here meat is partaken of for which fodder is required; but that is not the question—here principles are involved which must guide practice. The agricultural preceptors do not teach the planting of fodder with the view to obtain meat, but in order to have *dung*; and by this they prove that they do not understand a scientific law. In fixing a scientific principle, the first question is, not whether it is advantageous, but whether it be true? In scientific agriculture *dung*

no longer exists. All the ideas conveyed by this word are now exploded. Like the word *phlogiston*, which became obsolete at the end of the last century, as long as it was not known what phlogiston was, it served as an aggregate term to bind together a number of unknown causes to render them comprehensible. After it was ascertained what phlogiston represented, the right ideas were substituted, and the explanation of phenomena became true and reliable. Wood does not burn otherwise than formerly, air is what it was, water moistens as before; but what immense progress the human race has made since the right conception of air, oxygen, and the process of combustion took the place of the word phlogiston? A similar, but greater and more blessed advancement, must follow from the right knowledge or perception of the nutritive process in plants and animals; and it is as absurd for a chemical teacher to explain phenomena by phlogiston, as it would be for the farmer to employ the word dung in explanation of any agricultural process; for, in the place of this word, which is now without meaning, the word manure or compost is now substituted, expressing that for each plant there are certain ingredients serving as food, from the great effect of which the phenomena must be explained.

THEORY OF MANURES.—To understand the part which manures play in rendering soils productive, recourse must be had to the analysis of plants themselves. The composition of these will necessarily indicate the materials which must be supplied in order to promote their healthy growth. Now, when soils are submitted to the action of fire, it is found that there is an organic portion which burns off completely, and a residual one incapable of combustion, consisting of mineral substances. The same result follows the action of heat on plants. Healthy plants invariably contain a certain number of these mineral ingredients, and in fact always the same substances; the nature and quality, or the varying proportions of which, are ascertained by finding the composition of the ashes of the plants. The organic portion, dissipated by heat, consists mainly of the elements carbon, hydrogen, nitrogen, and oxygen, which produce by their union the various proximate principles of which plants are composed. The development of a plant, therefore, requires the presence of bodies capable of furnishing carbon, nitrogen, water or its elements, and the mineral matters which are likewise essential to vegetables. The latter ingredients can only be derived from the soil, but the supply of the elements which form the organic part may be quite independent of the soil. Lichens, which were at one time supposed to be destitute of roots, have been shown to be possessed of these organs with seemingly greater power than those of trees and herbs: for they are able to disintegrate and take up the necessary portions of the rocks to which they are attached, and fix them as a part of their constitution. Their organic constituents under these circumstances can come from only one source, namely, the atmosphere.

Origin of the Organic Portion of Plants.—As carbon the essential ingredient of organic bodies, is in its separate state altogether insoluble in water, it is plain that this element must be presented to plants in

such a form that it can be easily absorbed. This can readily be effected when the carbon is in the form of a complex compound quite soluble in water, or in the simple state of carbonic acid, a gas which is also freely dissolved by water. Hence have arisen two schools of vegetal physiologists—the one holding that organic substances which can be dissolved by water, are by its means conveyed through the rootlets of plants, and contribute directly to their nourishment equally with carbonic acid; the other holding that though such complex organic substances may pass in solution through the roots into the interior of plants, yet they in no way contribute to their nourishment, but must, previously to entering the plant, be decomposed into carbonic acid before they can be utilized. In other words, one school asserts that the carbon of plants is derived from soluble organic substances, as well as from carbonic acid; the other, that it is derived from carbonic acid *alone*. To the first school belong SAUSSURE, BOUSSINGAULT, MULDER, and PAYEN; to the second, LIEBIG and his followers.

The Humus theory of the Nutrition of Plants.—All plants and vegetal structures, after death, undergo decomposition by fermentation, and by a slow process of combustion, called by LIEBIG *eremacausis*. By these processes they lose carbon as carbonic acid, and are gradually converted into a dark-brown matter, which is known by the name of *humus*. Under this designation is included a variety of bodies, which have different chemical constitutions. Humus exists in larger quantities in virgin soils, and as such soils are noted for their fertility, the presence of this matter came to be regarded as the source of fertility of all soils. It was considered to be the principal nutriment of plants. The water of the soil, it was believed, dissolved the carbonic acid produced by the conversion of the vegetal fibres into humus, and those portions of humus soluble in water; and both of these, being absorbed by the roots of plants, contributed directly to their nourishment. Hence farmers added vegetal manure in large quantity to the soil, with the view of providing food for their intended crops. Want of space will not permit the discussion of the humus question. It will be sufficient to notice the objections brought against it by the supporters of the opposite views of the nutrition of plants. *First*, Springs of water arising out of the richest vegetal mould are quite clear, and contain no humus in solution. *Second*, Not the slightest ground exists for the belief that those substances called ulmin, humic acid, humin, *et cetera*, products of decomposition of vegetal matter by alkalies, exist in nature, in the form, and endowed with the properties, of the organic constituents of mould; and there is no proof that one of these exerts any influence on the growth of plants. *Third*, The experiments of SAUSSURE, which are generally adduced in favor of the humus theory, only show that the quantities of soluble organic substances taken up by the roots of plants, are just in the proportion in which they would run through filters. Thus, sulphates of the alkalies, which percolate a filter faster than acetate or nitrate of lime, were also taken up in greater quantity by the roots of plants. Sugar dissolved in water filters more easily than gum, and much more so than humus extract;

plants took up twice as much gum, and four times as much sugar as humus extract. *Fourth*, Granting that water does dissolve certain organic matters as well as carbonic acid, and convey them into the interior of the plant, it does not follow that such organic matters contribute to their growth. The roots of plants may absorb all soluble matters, organic as well as inorganic, with which they come in contact, yet only such portions be retained as are necessary to their organism; the remainder being returned to the soil. Did this power of selection not exist, the quantity of mineral constituents in plants, for example, would soon become enormous. The soluble organic matter, with the surplus mineral matter, is again returned to the soil. *Fifth*, There is great probability that the roots of plants have the power of selection, for as yet, even in the outer cells of the rootlets, not a trace of humus extract has been actually discovered. The presence of a substance resembling humic acid found in some diseased plants, is no argument in favor of its general presence.

The second theory of the supply of carbon to plants, rejects altogether the intervention of soluble organic matters. Woody fibre in the soil, by the access of oxygen, gives rise to carbonic acid. If this carbonic acid be removed, and a fresh portion of oxygen be admitted, a fresh portion of carbonic acid will be formed. This process is slow, and the presence of water is necessary to its maintenance. Woody fibre in this progressive state of *eremacausis*, is called humus, and when the decay is complete, and there is no longer formed any carbonic acid by the access of oxygen, there is left a brown coal-looking substance, which is mould. In every fertile soil there is, therefore, an atmosphere of carbonic acid surrounding every particle of decaying humus. This is dissolved by water in the soil, and at once absorbed by the roots of plants. By loosening the soil all round the roots, the access of air is accelerated, and a further portion of carbonic acid is the result. The roots, from the first moment of their formation, extract from the soil their proper nourishment, namely, the carbonic acid generated by the humus. As soon as the leaves have appeared, they also begin their functions by absorbing carbonic acid from the air. The quantity of this gas in the atmosphere, amounting to about one-tenth per cent., appears to be a trifling source of carbon. But when the immense mass of the air is taken into account, and it is recollected, that by the law of diffusion of gases, carbonic acid is in the same proportion in all parts, it can easily be shown by calculation that the atmosphere contains no less than three thousand and eighty-five billion pounds of carbon—a quantity which greatly exceeds the weight of all the plants existing in the world. This amount of carbon is, therefore, more than adequate for the growth of all plants, even if they were confined to this source of supply alone.

When a plant is fully developed, and the organs by which it obtains food from the atmosphere are formed, it may be said to be independent of the soil for its carbon. But as the functions of the organs of plants cannot be conceived to cease for a moment during their life; and as soils in which plants vegetate vigor-

ously always contain moisture, holding in solution carbonic acid, either produced within the soil, or brought to it by rain from the atmosphere, it follows that plants during their life must constantly absorb carbonic acid by their roots as well as by their leaves. It is thus seen, that on the one hand, a plant when placed under peculiar circumstances can depend on the carbonic acid of the atmosphere alone for its carbon, and that it has an abundant supply of this element in the air; yet under the ordinary normal condition of vegetal life, the supply must come from the carbonic acid of the soil as well as the air.

SOURCE OF NITROGEN OF PLANTS.—The quantity of nitrogen present in plants is small when compared with their carbon, hydrogen, and oxygen. One hundred parts of hay, oats, and potatoes, when dried at 240°, contain respectively one and a half, two and a half, and one and a fifth parts of nitrogen. But, though existing in such small proportions, this element is one of the most important in the constitution of vegetal products which serve as food for animals; their value in the scale of nutrition rising with the quantity of nitrogen they contain. It has been a subject of considerable discussion of late years, whether the nitrogen of the air is not absorbed by plants, and contributes directly to their nourishment. In a memoir presented to the Academy of Sciences, VILLE affirmed that the nitrogen of the air is assimilated by plants. BOUSSINGAULT showed by a series of carefully-conducted experiments, that this supposition of VILLE was incorrect. A committee, of which CHEVREUL was reporter, was appointed by the Academy to investigate the point. They made a series of experiments which, they stated, resulted in favor of VILLE's views. Still later, BOUSSINGAULT reinvestigated the subject, and by a series of the most carefully-conducted experiments, appears to have settled the question; and though VILLE, by still more recent experiments, thinks his prior views confirmed, yet for the present the results obtained by the former lead to the conclusion, that nitrogen is not directly assimilated by plants. The nitrogen of plants can, therefore, be derived from only two sources, namely, from ammonia and nitric acid.

When a large quantity of rain water which falls after long dry weather, or melted snow is evaporated to dryness, with a little sulphuric or hydrochloric acid, the residue is found to contain ammonia, which can be detected by its peculiar odor, on the addition of a little slaked lime. This ammonia, which at all times exists in the air, is derived from the putrefaction of animal substances, and from numerous other sources, from which it is evolved chiefly as carbonate. It is very soluble in water; hence every shower of rain removes it from the atmosphere, which again receives a constant supply from the sources just stated. Ammonia is the last product of the putrefaction of animal bodies. But if this ammonia be placed under favorable circumstances, it undergoes *eremacausis*, or slow combustion. The oxygen of the air converts its hydrogen into water, and its nitrogen into nitric acid. There is another mode in which nitric acid may be produced, namely by the direct combination of its elements, nitrogen and oxygen, by

means of electricity. This effect is often observed in thunder-storms. There is thus a constant supply of nitrogen from the atmosphere, in the form of ammonia and nitric acid. The amount present in a given portion of air is very small; but the total quantity which may be derived from this source in a given time is not inconsiderable, when it is recollected, that a generation of a thousand million men is renewed every thirty years; and thousands of millions of animals cease to live, and are reproduced, in a much shorter time.

The ammonia and nitric acid in solution in water in the soil, are at once absorbed by the roots of plants, and in both forms assimilated by their organs for the production of the nitrogenized matters which they contain. This fact has been proved by many observers. The juice of maples, birches, tobacco-leaves, when evaporated with lime, emits a quantity of ammonia. The evolution of ammonia from the juice of beet in the process of clarifying by lime, is familiar to every beet-sugar manufacturer. The tobacco plant, sunflower, *Borago officinalis*, *Apium Graveolens*, contain in their juices considerable quantities of nitric acid in the form of nitrates. The presence of nitrates in the sap of plants has been supposed to prove that the nitrogen of the nitric acid is not employed in the organism for the production of compounds containing that element. But this conclusion cannot be drawn from the presence in the juice of nitric acid, any more than from the presence of ammonia and carbonic acid. It only proves that these substances after absorption have not yet undergone decomposition and fixation in the plant, or that they exist as a surplus not required for its further development.

The employment of animal manures for those crops which are most important as food of animals, is a satisfactory proof that their nitrogen is derived from ammonia. An increase of animal manure gives rise not only to an increase in the number of seeds, but also in the proportion of those substances in them which contain nitrogen. One hundred parts of wheat grown on a soil manured with cow dung, a manure which contains the smallest quantity of nitrogen, afforded only 11·95 parts of gluten, and 62·34 parts of starch; whilst the same quantity grown on a soil manured with human urine, which is highly nitrogenized, afforded the maximum of gluten, namely, 35·1 per cent. In a subsequent portion of this article, the question of the supply of ammonia to plants will be again noticed.

In the foregoing remarks it is seen, that the conditions necessary for the production of the organic constituents of plants are moisture, and the presence everywhere of bodies to furnish carbon and nitrogen. The essential food of plants must not be one which is found in one place, and is absent from another. Wherever water is, there must be found these sources of carbon and nitrogen. No substances fulfil these conditions but carbonic acid and ammonia. Hence the whole theory of the nourishment of a plant, so far as the formation of its organic portions is concerned, consists in the constant supply of carbonic acid and ammonia, and as a substitute for the latter, nitric acid, from which carbon and nitrogen are assimilated.

THE INORGANIC FOOD OF PLANTS.—Experience

has shown that, however abundantly carbonic acid and ammonia may be supplied to plants, yet they cannot live upon these alone. Seeds sown in sand, and aspersed with water impregnated with carbonic acid and ammonia, arrive at a certain stage of growth, and then begin to droop and die. The inorganic matter left on burning a plant is as necessary for its growth as carbonic acid and ammonia. The bones, muscles, and blood of animals cannot exist without a constant supply of inorganic elements, and these must be derived ultimately from plants which form the food of graminiferous animals. Hence plants must store up within themselves inorganic constituents for the wants of animals, as well as for themselves. The number of these inorganic constituents is comparatively small. They are chiefly potassa, soda, lime, magnesia, oxide of iron, and silica, phosphoric and sulphuric acid, and chlorine. It is not known what particular part they play in the vegetal organism; but that they are essential is proved by the power which is conferred on plants of selecting such substances as are necessary for the growth of their different parts. Sea-water contains a large quantity of soda, and but a mere trace of potassa; yet some sea-weeds, as dulse, contain much potassa and little soda; thus proving that the plant has selected out of a mass of soda the potassa, which is necessary for the perfect structure of its seed.

In the first instance, the roots of plants may take up all substances in solution without selection. But this action is not one of simple imbibition as in the case of sponges. LIEBIG, in a recent memoir, maintains that the spongioles, in obtaining their supply of saline matter, exert a real decomposing action on certain ill-defined compounds, which the saline matter forms with the insoluble constituents of the soil. Those substances which are conveyed to plants in solution are retained in greater or less quantity, or are entirely rejected when not fit for assimilation.

Carefully-conducted experiments have proved, that on whatever soil grown, if a plant is healthy and ripens its seed, the quantity and kind of ash which it contains are, within certain limits, and with certain admissible variations, nearly the same. Further experiments have also shown, that the ash left by two different species of plants grown on the same soil, is never exactly the same. Thus silica, alkaline and earthy phosphates, form invariable constituents of the seeds of all kinds of grasses; and bulbous and tuberous roots are characterized by the large quantity of potassa and soda they contain. The different parts, too, of the same plant have variable proportions of inorganic matter. Such constituents, according to LIEBIG, appear to exist in the smallest quantity in those parts of a plant in which the process of assimilation is most active, as in the mass of woody fibre; and their quantity is greatest in those organs, the office of which it is to prepare substances conveyed to them for assimilation by other parts. Hence there is a larger quantity present in leaves than in branches, and more in the latter than in stems.

The quantity of ash left by the different parts of cultivated plants is seen by the following table:—

PROPORTION OF ASHES LEFT BY ONE HUNDRED POUNDS OF THE SEEDS, HUSKS, AND STRAWS, OF THE USUALLY CULTIVATED GRAINS.

When the composition of the ash thus left by plants is examined, several important points are ascertained. It is seen that though silica is not always wanting for the grain of the corn-bearing plants and grapes, yet that it is absolutely necessary to, and may be said to be the characteristic mineral ingredients of their stems. In the ash of the grain of wheat it amounts to one per cent., whilst in the ash of its straw the quantity varies from forty to eighty per cent.

Phosphoric acid is the characteristic ingredient of the seeds of plants. It forms about one-half of the ash of the grain of the different cereals, when burnt with their husks, but is seldom present in any considerable quantity in their ripe straws.

As the ash of the stems of cereals is characterized by silica, so the ash of the stalks of leguminous plants, and the tops of the potato and turnip, are remarkable for the quantity of lime they contain.

Root crops have also their characteristic mineral ingredients. Potassa and soda, which are present to the extent of thirty per cent. in the ash of cereals, and

about forty per cent. in the ashes of beans and peas, amount to about fifty to sixty per cent. in the ash of the turnip and potato. Thus larger quantities of the alkalies are present in roots than in other crops raised for human food.

The following table shows the amount of essential inorganic ingredients contained in one hundred parts of the ashes of the commonly cultivated plants:—

JOHNSTON has made elaborate calculations in his agricultural lectures, to show the enormous amount of mineral constituents removed from the soil by cultivated plants. Only a few examples, by way of illustration, need be taken:—

Mineral Constituents removed per acre of Wheat.
—If the produce of a field of wheat be taken at the rate of twenty-five bushels per imperial acre, weighing sixty pounds a bushel; and if the straw averages twice the weight of the grain, then the quantity of inorganic matter carried off the soil by the crop will be, per acre:—

	Pounds.
In one thousand five hundred pounds of grain at two per cent. of ash,.....	30
In three thousand pounds of straw at six per cent.,.....	180
Total,.....	210

The composition of the matter thus carried off,

according to the mean of analyses of ashes given in the table, will be, in pounds:—

	Grain.	Straw.	Total.
Potassa,	7.15	22.44	29.59
Soda,	2.73	0.29	3.02
Lime,	0.85	12.09	12.94
Magnesia,	3.63	6.89	10.52
Oxide of iron,	0.20	2.35	2.55
Phosphoric acid, ...	15.02	5.54	20.56
Sulphuric acid,	0.07	10.49	10.56
Chlorine,	—	1.97	1.97
Silica,	0.35	117.94	118.29
	30.00	180.00	210.00

Mineral Constituents removed per acre by a Crop of Barley.—If the produce of an imperial acre of barley amount to forty bushels, each weighing fifty-three pounds, and if the straw averages one-fourth more than the weight of the grain, then the proportion of inorganic matter removed from each acre by a crop of barley, will be—

	Pounds.
In two thousand one hundred and twenty pounds of grain at two and a half per cent. of ash, ..	53
In two thousand six hundred and fifty pounds of straw at six per cent. of straw,	160
Total,	213

The composition of this ash will be found by the table to consist of—

	Grain.	Straw.	Total.
Potassa,	7.24	10.29	17.53
Soda,	4.32	0.92	5.24
Lime,	1.39	15.53	16.92
Magnesia,	3.97	5.25	9.22
Oxide of iron,	0.79	1.35	2.14
Alumina,	0.12	2.26	2.38
Phosphoric acid, ...	20.74	5.02	25.76
Sulphuric acid, ...	0.05	2.66	2.71
Chlorine,	0.02	1.58	1.60
Silica,	14.36	115.14	129.50
	53.00	160.00	213.00

Mineral Constituents removed per acre by a Crop of Turnips.—A good crop of turnips varies from twenty

	Grain.	Straw.	Bulbs.	Tops.	Hay.	Total.
Potassa,	14.39	32.73	142.66	88.82	38.22	316.82
Soda,	7.05	1.21	17.31	16.76	12.05	54.38
Lime,	2.24	27.62	46.24	72.14	44.45	192.65
Magnesia,	7.60	12.14	18.16	9.58	7.09	54.57
Oxide of iron,	1.11	5.96	4.35	2.67	0.58	14.67
Phosphoric acid,	35.76	10.56	25.77	28.80	15.12	116.01
Sulphuric acid,	0.12	13.15	46.24	38.81	9.20	107.52
Chlorine,	0.02	3.55	12.24	49.75	4.06	69.62
Silica,	14.71	233.08	27.03	2.67	78.23	355.72
	83.00	340.00	340.00	310.00	209.00	1282.00

This table is highly important, as showing the enormous quantity of soluble minerals removed from soils by cultivated crops. If the crops were removed from the ground, and no means were taken to return to the soil in some form the mineral constituents thus constantly taken off, the inevitable consequence would ultimately be *utter sterility*.

APPLICATION OF MANURES.—The facts adduced in the preceding pages tend to show what is the real nature of manures, and in what manner they act. They are the food of plants; hence the necessity of understanding, in the first instance, the mode in which plants are

to forty tons of bulbs per imperial acre. If twenty tons be taken as an average crop, and if the tops, which always vary much in the proportion they bear to the clean bulbs, be assumed as equal to one-third of the weight of the bulbs, the inorganic matter carried off by a crop of roots and tops will be as follows:—Twenty tons of bulbs contain two tons of dry matter, leaving seven and a half per cent. of ash, or about three hundred and forty pounds. Six tons and a third of tops contain one thousand eight hundred and fifty pounds of dry matter, leaving seventeen per cent. of ash, or about three hundred and ten pounds. Bulbs and tops thus remove in all six hundred and fifty pounds of mineral matter, having the annexed composition, in pounds:—

	Bulbs.	Tops.	Total.
Potassa,	142.66	88.82	231.48
Soda,	17.31	16.76	34.07
Lime,	46.24	72.14	118.38
Magnesia,	18.16	9.58	27.74
Oxide of iron,	4.35	2.67	7.02
Phosphoric acid, ...	25.77	28.80	54.57
Sulphuric acid, ...	46.24	38.81	85.05
Chlorine,	12.24	49.75	61.99
Silica,	27.03	2.67	29.70
	340.00	310.00	650.00

Mineral Constituents removed per acre by a Crop of Hay, consisting of one ton of rye grass, and half a ton of red clover:—

	Pounds.
Potassa,	38.22
Soda,	12.05
Lime,	44.45
Magnesia,	7.09
Oxide of iron,	0.58
Phosphoric acid,	15.12
Sulphuric acid,	9.20
Chlorine,	4.06
Silica,	78.23
	209.00

The total mineral constituents removed from the soil by this four years' rotation of crops, will be, in pounds:—

	Grain.	Straw.	Bulbs.	Tops.	Hay.	Total.
Potassa,	14.39	32.73	142.66	88.82	38.22	316.82
Soda,	7.05	1.21	17.31	16.76	12.05	54.38
Lime,	2.24	27.62	46.24	72.14	44.45	192.65
Magnesia,	7.60	12.14	18.16	9.58	7.09	54.57
Oxide of iron,	1.11	5.96	4.35	2.67	0.58	14.67
Phosphoric acid,	35.76	10.56	25.77	28.80	15.12	116.01
Sulphuric acid,	0.12	13.15	46.24	38.81	9.20	107.52
Chlorine,	0.02	3.55	12.24	49.75	4.06	69.62
Silica,	14.71	233.08	27.03	2.67	78.23	355.72
	83.00	340.00	340.00	310.00	209.00	1282.00

nourished. Plants must be furnished with matter to build up their organic and inorganic portions. Complex organic matters, as has been stated, do not nourish plants, until decomposed into carbonic acid, water, and ammonia. These substances exist in the air; this source might, therefore, be trusted for their supply, but a double source of supply, from air and soil, undoubtedly causes greater activity in a given time in vegetation. Inorganic constituents can come from the soil alone. Of the two kinds of food of plants, the gaseous and inorganic, which it may be necessary to add to a barren soil, by far the most important and indispensable is the latter.

The various facts already discussed, and the essential points connected with the application of manures, cannot be better summed up, than in the words of LIEBIG in his *Principles of Agricultural Chemistry*.

In the shape of agricultural produce of a field, the entire amount of those constituents which have become ingredients of plants is removed from the soil. After a series of years, and a corresponding number of harvests, the fertility of the soil or field diminishes. The change which is found to have taken place in the composition of the soil after harvest, is the probable cause of its diminished or lost fertility. By means of solid and liquid manure, or the excreta of men and animals, the lost or diminished fertility of the land is restored. Solid or farmyard manure consists of decayed vegetal and animal matters, which contain a certain proportion of the constituents of the soil. The excrements of men and animals represent the ashes of the food consumed, and which has been derived from the supposed soil. The urine contains the soluble, the solid excreta the insoluble constituents of the soil derived from the crops used as food, and reaped from the soil. By adding these to the soil, it recovers those constituents which have been removed from it in the crops.

Thus the restoration of its original composition is accompanied by the restoration of its fertility. It is therefore certain that one of the conditions of fertility in a soil, is the presence in it of certain mineral constituents. A rich fertile ground contains more of these than a poor barren one does.

Vegetal and animal matters, and animal excreta, when in the soil, undergo putrefaction and slow oxidation. The nitrogen of their nitrogenized constituents is changed in the process of putrefaction and decay into ammonia, and a small part into nitric acid, which is the product of the oxidation or decay of ammonia. There is every reason to believe that nitric acid can replace ammonia, as a source of nitrogen to plants. In animal manures, therefore, not only are plants supplied with the mineral substances which the soil must yield, but they are also supplied with those parts of their food which the plant obtains from the atmosphere. The latter supply is a clear addition to that which the air at all times affords.

The solid and liquid parts of the food of plants contained in the soil must enter the roots in solution in water, or, in the case of those substances not soluble in pure water, in water containing carbonic acid or some salt of ammonia. Hence animal manures, undergoing decay in the soil, render the air and water which pass through it richer in carbonic acid and salts of ammonia. They thus not only supply plants with a certain amount of their mineral and atmospheric food, but also provide them with those substances—carbonic acid and ammoniacal salts—which are the most indispensable for the introduction into the vegetal organism of the mineral constituents, which, by themselves, are insoluble in water, and this to a larger amount in the same time than could be effected without the co-operation of decaying organic matter. The mineral constituents which all plants, without exception, require for their nutrition, are phosphoric acid, sulphuric acid,

the alkalies, lime, magnesia, and iron. Some important genera require silica. Those which grow on the seashore and on the sea require chloride of sodium, soda, and iodides of metals. In some genera, the alkalies may in part be replaced by lime and magnesia, or these latter by the alkalies. All these substances are included in the term mineral food of plants; carbonic acid and ammonia being termed the atmospheric food.

From some recent experiments respecting the capacity of soils for absorbing the soluble constituents of manure, LIEBIG has been led to a new theory respecting the nutrition of plants, and which is quite opposed to the foregoing view. The inference deducible from the Baron's experiments is as follows:—That land plants do not receive their food from a solution of the ingredients already present in the soil, but that they abstract or absorb it *directly from the soil itself*, through the joint agency of water and of a force inherent in the roots.

The different substances necessary to the growth of a plant, or the different articles of their food, are all of equal value; that is to say, if one out of the whole number be absent, the plant will not thrive. The soils which are proper for the cultivation of all sorts of plants, contain all the mineral constituents necessary for them. But of two soils containing equal quantities of these mineral ingredients, one may be considered rich or fertile, and the other poor or barren, if in the former case they are present in a form soluble in water, and in the latter are insoluble. All soils adapted for culture contain the mineral food of plants in these two states. The quantity of the soluble ingredients can be increased from the insoluble, in other words, the soil made more productive by mechanical means. This process is called weathering, or fallow; the insoluble minerals being disintegrated by the aid of carbonic acid, oxygen, and water. Hence stagnant water in the soil—undrained fields—which excludes the air from access to the insoluble compounds, is an obstacle to this process of weathering. Land in which the necessary mineral constituents are not present in any form, cannot be rendered fertile by fallow or by ploughing.

As different kinds of plants require for their development in some cases the same mineral substances, but in unequal quantities, a soil may become barren for any one kind of plant, when by a series of crops one only of these constituents, as for example, soluble silica has been so far removed that the remaining quantity is no longer sufficient for a crop; but it may still contain sufficient mineral constituents for another kind of crop which does not require soluble silica. A third sort of plant may thrive on the same soil after the second, if the remaining mineral constituents suffice for a crop of it. Upon this fact depends the rotation of crops.

The nutritive substances necessary to the life of a plant must act together within a given time, if the plant is to attain its full development in that time. The absence or deficiency, or the want of available form in one necessary constituent, renders the others which are present ineffectual, or diminishes their efficacy, and the soil is rendered barren for all those crops to the life of which that one constituent is indispensable; but fertility is communicated if that one substance be added in due

quantity, and in an available form. The supply of more atmospheric food—namely, carbonic acid and ammonia—by means of ammoniacal salts and humus, than the air can furnish, increases in a given time the efficacy of the mineral constituents present in the soil. In a soil rich in the mineral food of plants, the produce cannot be increased by adding more of the same substances. In a soil rich in the atmospheric food of plants, rendered so by manuring, the produce cannot be increased by adding more of the same substances.

From land rich in mineral constituents, there may be obtained in one year, or for a series of years, by the addition of ammonia alone, in its salts, or of humus and ammonia, rich crops, without in any way restoring the mineral substances removed in these crops. The duration of this fertility depends on the supply of the available mineral constituents existing in the soil. The continued use of these manures produces sooner or later an exhaustion of the soil. If after a time the soil is to recover its original fertility, the mineral substances extracted from it by the crops in a series of years must be again restored.

These admirable propositions furnish the key to the application of manures. The continued fertility of a soil for all kinds of crops, depends on the constant return to it of *all* the mineral constituents removed by the different crops. If a great increase in one crop has been effected by the application of one manure alone—for example, of phosphate of lime, or of ammonia—this only proves that all the other ingredients necessary to that crop have been present in sufficient abundance in the soil. The agriculturist would not be warranted by the success of this one experiment in repeating it too often, or the infallible result would be the ultimate exhaustion of his land. No single mineral substance, in however large quantities, can confer *permanent* fertility. This result can only be attained by the combination of all those mineral salts found in the ashes of plants, or by the use of a compost, such as carefully prepared farmyard manure, which contains in itself these different ingredients.

Here perhaps may be the proper place to notice, that the views of the nature of manures advanced by LIEBIG have been combated by LAWES and GILBERT, who have endeavored to show by a series of experimental results, that this so-called mineral theory of LIEBIG is an entire failure as a guide to the use of manures in practical farming. In some respects their views may be said to be diametrically opposed to those of LIEBIG. As a rule the latter holds, that plants when abundantly provided with their mineral constituents in an available form, may get their carbon and nitrogen from the air, though it does not follow that this source alone is to be trusted to for these ingredients; the former think that their experiments warrant them in concluding, that minerals supplied to wheat crops in much greater quantity than equivalent to those taken off in the increased produce, were only available so long as there was a liberal provision of nitrogen in the soil; that when this artificially-supplied nitrogen was exhausted, the minerals remained inactive and useless; that in the very cases where minerals gave an increased produce, in the well-defined limit to their

action which is indicated, there is further proof of the necessity of an artificial supply of nitrogen in the soil for the increased production of corn, and the incapacity of the mineral supply to yield any increase, excepting when nitrogen is thus provided. They further concluded from their experiments, that there is a fallacy in supplying to plants a manure founded on the percentage composition of their ashes: for in the case of the turnip, which shows, both in the leaf and in the bulb, a proportion of alkalies to phosphoric acid of from four or five to one, it might be thought that alkalies were, therefore, the more appropriate and special manure for turnips, whereas common practice has determined in favor of phosphoric acid, and their own experiments proved that the addition of alkalies to superphosphates on turnips did not increase the return.

LIEBIG, in his recent work on the Principles of Agricultural Chemistry, has clearly proved that the conclusions of these gentlemen are based on the most palpable fallacy of selecting for their experiments a portion of land which, so far from being in a practically and agriculturally exhausted state, was by the showing of their own experiments, still so rich in mineral constituents as to have yielded, though unmanured throughout, in the seventh year a crop which exceeded by seventy-seven pounds of grain and five hundred and ninety-nine pounds of straw that of the first year. The conclusion drawn by them from their results, that nitrogenized manures are peculiarly adapted for the culture of wheat, is true only for their own land under the given circumstances, namely, containing a sufficiency of available minerals, and would entirely mislead the practical farmer if he applied it to other land of different quality, and placed in different preliminary conditions. For it can be proved, as LIEBIG states, in the same way, and by facts equally decisive, that ammoniacal salts alone, in thousands of wheat fields, do not in the smallest degree increase the produce; and that in thousands of other such fields, these salts do increase the produce for a year or two; and that then a further application of them to the same land is found to be utterly without effect; that salts of ammonia increase the produce only if the mineral constituents be present in the soil in due quantity, and in an available form, by rendering those minerals more soluble, and accelerating their action in a given time. Hence the use of ammoniacal salts alone tends rapidly to exhaust a soil, and if used by themselves without any mineral manure, no cultivation whatever can be permanently kept up.

In the opinion of LIEBIG, the experiments of LAWES and GILBERT, so far from disproving the mineral theory, afford, on the contrary, the strictest and most satisfactory proof of its truth. The reader is referred to LIEBIG's able work for a clear and distinct view of what is really his mineral theory, and to a paper by the same author in defence of his views, in the seventeenth volume of the Journal of the English Agricultural Society.

Farmyard manure is taken as the type of manures, because it contains all the constituents removed from the land, and again restored to it in a form in which they can be made rapidly available. The carbonic

acid and salts of ammonia produced by its decomposition, cause water to dissolve more rapidly the mineral constituents. Compounds of ammonia would thus seem to have two actions in the nourishment of plants, namely, *First*, As a source of nitrogen; *Second*, As a solvent for certain important mineral constituents of the soil.

An artificial mixture can be theoretically compounded to take the place of farmyard manure, but it must contain all its mineral constituents. The agriculturist must return to the land whatever has been removed from it; for it has been laid down as a rule, that no part of the constituents of a rich soil can be removed without making compensation, but at the cost of sooner or later impairing its fertility.

It is not to be supposed from the preceding, that practical empirical experiments with special manures are to be altogether condemned as useless. They are, on the contrary, highly valuable under certain conditions. The error lies in elevating the practical results into general laws. Experience has shown, for example, that nitrogenized manures have produced large crops of wheat, and superphosphate of lime has had the same effect with turnips. The experimenters, forgetting to inquire whether these results are universally true, or true only under certain conditions, have emphatically pronounced nitrogen and superphosphates to be the manures for these crops. Other experimenters have come forward and shown that nitrogenized manures in their hands have not always had good results, and bones in the hands of others have not answered at all, either for turnips or anything else.

These contradictory conclusions embarrass the practical farmer, but the man of science sees that the difficulty lies in having taken these special results for general truths. His science has taught him, that there is a law more general still for the successful cultivation of wheat and turnips under all circumstances, namely, that along with nitrogen and phosphates, they must have *all* their mineral constituents provided for them. He is able thus to show, that the application of nitrogen and that of phosphates are mere special conditions for the successful cultivation of these two crops, which can only hold good when the more general and universal conditions are fulfilled. Instead of altogether rejecting the practical results obtained by others, he endeavors to ascertain if the failure of the special rule, in any given case, does not arise from the land not fulfilling the conditions of the more general law.

Rules for the application of Artificial Manures.—The following rules have been given by W. Hannam, as useful in carrying into effect the judicious application of artificial manures:—

In all mixtures designed for application in autumn or winter, the ammonia or nitrogen should be supplied in a form that would as far as possible prevent its operating too quickly—for example, it would be preferable to supply the nitrogen in union with other organic matter, as in rape-dust, bones, woollen rags, partially decomposed blood, guano, mixed with charcoal, gypsum, *et cetera*, rather than in the shape of salts of ammonia, which are so speedily soluble:

That all winter dressings of artificial manure should be mixed in the soil:

VOL. II.

That all mixtures in which the ammonia exists in a saline form, should be applied as a spring top-dressing upon the crop, if possible in wet weather during the third or fourth week of April:

That all mixtures containing organic matter rich in ammonia, as rape-dust or guano, if applied with spring crops, should be harrowed in immediately; and if applied as a top-dressing, should be used only in wet weather:

That spring top-dressings, which contain organic matter, should be applied earlier than those purely saline:

That mineral manures which contain their phosphates and alkalies in the most soluble state, should be applied in spring crops:

That where a heavy saline dressing is required in spring, upon wheat, potatoes, or grass, it is advisable to apply it at two distinct periods about a month apart, as in April or May.

In a recent paper, just received from Baron LIEBIG, and which contains numerous experimental data, the good effects of chloride of sodium, nitrate of soda, and salts of ammonia are shown to depend, not so much on their intrinsic value, as upon their capacity of dissolving large quantities of phosphate of lime, thus rendering this important salt easily conveyable to the roots of the plants.

Absorbent power of soils for Manures.—At the time these rules were given, the absorbent powers of soil were not then known, and precautions were supposed to be necessary in the application of manures, which experiment has since shown to be superfluous.

THOMPSON first pointed out the power possessed by soils in arresting salts of ammonia, and WAX has extended the same observation to all the mineral constituents which serve as food of plants. He found that, without exception, the bases of the alkalies and alkaline earths were removed from their acids, and retained by soils; the acids, such as sulphuric and hydrochloric passing away in solution in combination with lime. There was one remarkable exception in the case of phosphoric acid, which never passed away like sulphuric acid, but was retained by the soil, though presented to it in the form of a soluble alkaline phosphate. Nitric acid, on the other hand, now and much employed in agriculture, was found to pass rapidly away. This acid, when in combination with potassa, soda, or ammonia, was found to give up these bases, and to pass off in combination with lime. In prosecuting his inquiries to find out what constituents of soil possessed this extraordinary power, he ascertained that it was due to clay alone. It is not a mere power of absorption, as is the case with charcoal, but a chemical action. It does not appear, however, that the whole mass of clay acts, but portions containing silicate of lime, which, in contact with the alkaline salts, gives up a portion of its lime to their acids, and retains their bases as double silicates. Whether or not this is the true explanation, the fact is certain, that clay is the absorbing material. Hence, sandy and gravelly soils not possessing a sufficiency of clay, might be expected to be less retentive of manure. The experience of all farmers proves this fact; such sandy and gravelly land being said by them not to hold

manures. On such soils, manures require to be applied more frequently and in smaller quantities than in stiffer clay soils, which have the power of retaining the manure for several crops.

A knowledge of this property of clay explains the fertility attending the application, as is practised in Norfolk, of clay to sandy soils. From some recent experiments and analyses, LIEBIG doubts whether the clay is the only absorbing material. In the Editor's opinion, the *physical condition* of the soil must have something to do with it.

In the case of ammonia, the supply to the soil is not derived alone from the manures, or the ammonia of the air brought down by rain; but absorption of this gas goes on continuously from the atmosphere by contact alone. LIEBIG, in 1846, caused the analysis of twenty soils to be made in his laboratory, from which he ascertained the enormous amount of ammonia really present in every soil. One acre of the most unfruitful soil taken, to the depth of only ten inches, contained more than a hundred times, and one acre of fertile soil, as much as from five hundred to a thousand times more nitrogen than is required for the heaviest crop of wheat, or than is given to it in the most liberal supply of manure.

If the experimental results of WAY be correct, it would appear that unnecessary alarm was felt a short time ago, that the system of tile-draining, which was so universally adopted with the happiest effects to agriculture, would ultimately tend to exhaust the soluble mineral ingredients of the soil.

In his paper on the composition of land-drainage water, WAY has, by a series of carefully-conducted analyses, found that the substances which exist in drainage water in largest proportion are those which are most abundant in the soil, namely, lime and magnesia, soda, and sulphuric acid; and that, with the exception of nitric acid, none of the essential mineral food of plants is found in any quantity. If 42·4 per cent. of the annual rain pass through the soil, and the latter be taken at 25 inches, the quantity of drainage water from an acre of land would amount to about two hundred and forty thousand gallons. Even where the land is very highly manured, he shows that this large quantity of water removes from the soil only inconsiderable quantities of the most important mineral ingredients of soils, namely, potassa and phosphoric acid. The quantity of ammonia carried off is very small; but nitrogen in the form of nitric acid, especially in highly manured land, is to be found in large quantity in the water of land drainage. VOELKER showed that clay soils exert this action on complex organic mixtures, such as the drainings of dunghills, as well as on simple salts. From the most highly mixed manuring substances, not only ammonia from the ammoniacal salts, but potassa, phosphoric acid, and all the essential ingredients of the food of plants, are all removed from solution in water, and retained in the soil.

These experimental results are fundamental facts of the utmost importance to agriculture. They explain the advantage of drainage, by showing that the manure which would be carried off the surface of the undrained land into the water-courses, is carried down by the water which is passing into the drains of a drained

field, but is separated from solution by the soil through which it percolates. They show that the best mode of applying manures is that which causes the most uniform distribution of it, namely, as a liquid. For if salts of ammonia, when once applied to the soil, combine with it and remain fixed, water would seem to have no further power of uniformly distributing them, and hence the frequent irregularity of crops in manured fields. The fear has hitherto been, that by too early an application of manures to the land before the crop, there was a risk of loss, by evaporation and by rain. This is true to some extent for sandy soils, on which, it appears, the true guiding principle should be, for the manure to be applied frequently and in smaller quantities at once. The retentive power of clay, on the other hand, may be fairly trusted to keep all that is bestowed upon well-drained clay soils.

Classification of Manures.—Manures may be divided into two great classes, namely, general and special.

General manures include all mixed substances, whether of an animal or vegetal origin, which contain all the constituents necessary to plants for luxuriant growth. Such manures confer permanent fertility on a soil.

Under this class may be ranged—Farmyard Manure, Guano, Night-Soil, Sewage Manure, *et cetera*.

Special manures are those substances which contain only one or more of the constituents necessary to the growth of plants. They cannot confer permanent fertility on the land, but on the contrary, their exclusive and continued use tends to render it ultimately sterile, by enabling particular crops to remove more rapidly and largely those ingredients which are actually in the soil. To this class belong bones, blood, woollen rags, horns, fresh rape-cake, sea-weeds, gas-liquor, salts of ammonia and of the alkalies and alkaline earths, *et cetera*.

It would be quite out of place in an article of this kind, to discuss at length the various substances used as fertilizers. It will be sufficient to take from these two classes one or two examples of the most commonly-employed manures, and to give under each the principal points connected with their theory, management, and applications, from which the principles connected with the application of other manures may be inferred.

GENERAL MANURES.—Farmyard Manure—History.—The first attempt to restore fertility to the soil must have been by the use of the excrement of animals, and must date from an early period of the history of mankind. The art of husbandry, and the preparation of mixed manures for their fields, occupied much the attention of the Romans. Their writers inculcate the formation of two manure heaps, one to receive the fresh dung, the second for the old manure, which was applied to the field after being kept a year. Their manure was recommended to be placed in a hollow to collect moisture, and to be covered with straw to protect it from the weather. These good rules were forgotten during the long period which succeeded the extinction of Roman civilization. It is only of late years that science has been brought to bear on this subject, and with that success which is its invariable accompaniment. The study of the composition, and of the chemical metamorphoses that farmyard manure undergoes, has enabled

scientific men to suggest the best means of collecting, preserving, and applying it.

Theory of the action of Farmyard Manure.—It has long been an opinion of the practical farmer, that nothing can be a complete substitute for farmyard manure. This opinion is to a considerable extent justified by analysis, for it contains, with the exception of a portion of carbon and hydrogen, all the materials which have been removed from the soil by plants. It is formed for the most part of cows' dung, pigs' dung, and straw, mixed and trodden together. Where green crops are extensively grown and many cattle kept, cow dung forms a great proportion of the manure. The composition and value of farmyard manure will, therefore, vary much with the feeding and the animals. Thus, the manure of cattle fed on turnips is inferior to that of cattle fed on oil cakes; the manure of horses fed on straw and hay, is much poorer than that of horses fed on corn; the compound manure which has an excess of cattle excrement is less powerful than one with an excess of the dung of the horse; the compound manure which contains no night-soil, is less fertilizing than one with a proportion of it. An analysis of one specimen of farmyard manure cannot be taken as a general expression of its composition, which varies with the circumstances above stated. The only process by which an approximative idea may be formed of the fertilizing powers of a given quantity of farmyard manure, is to observe the kinds of animal excrement it contains, and the proportions in which they are mixed with each other, and with vegetal matters.

Farmyard manure which is either quite fresh, or has undergone so little fermentation as to retain its litter in an undecomposed, and but partially broken state, is known by the name of *long dung*. When it has been

thoroughly fermented, so as to have been changed into a rotten powdery or saponaceous mass, or is so free from litter as to consist almost entirely of solid excrement, it receives the name of *short dung*. Much controversy has existed among farmers, as to the relative merits of these two forms. An examination of the chemical changes which have taken place in this process, throws some light on these controversies. KOERTE found by experiment, that one hundred loads of fresh dung become reduced by fermentation and exposure as follows:—

	loads.
In 81 days 100 loads were reduced to	73·3
In 285 " " " "	64·4
In 384 " " " "	62·5
In 499 " " " "	47·2

In sixteen months the quantity had been reduced to less than one half, and the most valuable salts lost.

The reduction of weight of farmyard manure depends on two causes, namely, the elimination of gases by fermentation, and the loss of soluble matters by drainage. The latter, the least feared, is by far the most serious source of loss. The former has been shown by VOELKER to be not so destructive as was formerly supposed.

By making a thorough mixture of the litter, and dung of fresh or long dung, VOELKER obtained a sample for analysis, and for experiments with fermentation. By comparing the composition before and after fermentation, he arrived at some valuable conclusions.

Fresh farmyard manure, composed of horse, pig, and cow dung, about fourteen days old, and on which no rain had fallen, was found to consist, in round numbers, of two-thirds of water and one-third of solid matters.

This analysis of a fair average specimen of fresh farmyard manure, so far as an average can be taken of this substance, is instructive. It shows that farmyard manure is a perfect and universal manure, because it contains all the constituents which are required by the commonly-cultivated crops to bring them to perfection, and in states of combination which appear to be especially favorable to their luxuriant growth. It explains fully the slow action of fresh dung when compared with the effects of well-rotted manure; because the former contains only one-eighth of soluble matters as compared with the insoluble, whilst in the latter this quantity of soluble is much increased by fermentation, as will presently be seen. In this small soluble portion, the most important fertilizing substances are present.

The proportion of nitrogen in one hundred parts of the soluble organic matter, as compared with the insoluble, is as 6.04 to 1.92. The most valuable salts pre-

sent in considerable quantities are silicates of potassa and phosphate of lime.

The remarkable fact of the presence, in the watery solution, of phosphate of lime, usually considered an insoluble compound, is explained by the observation of WÖHLER, that bone-dust, moistened with a little water, in the course of a few days yields to water a considerable quantity of phosphate of lime, and this solubility rapidly increases with the putrefaction of the gelatine of bones. Hence, wherever earthy phosphates exist with organic matter, water will invariably dissolve a portion, progressively with the decomposition of the organic matter by fermentation. This fact is of the utmost importance to agriculture.

The effect produced on manure by fermentation is well seen by analysis. A well-mixed sample of rotten dung, of dark-brown color, at least six months old, and which was produced under the same circumstances as the fresh manure, was found to have the following composition:—

An examination of these two Tables shows that, during the fermentation of dung, the quantity of both soluble organic and soluble mineral matters rapidly increases; and that the proportion of ammonia and of phosphate of lime in these soluble matters also rapidly augments. Thus one hundred parts of dry soluble organic matter from fresh dung contain 6.14 of nitrogen, whilst one hundred from rotten dung contain 8.02, and the phosphate of lime is nearly doubled. The proportion of organic matter decreases as the fermentation goes on, but the loss is in carbonic acid and other non-essential gases. There is apparently no serious loss of ammonia by evaporation, as is commonly supposed. Direct experiments have shown that, in the cold, no ammonia is given off from the surface of farmyard manure, and

that a considerable amount of heat is necessary for this purpose. Now, as this occurs only in the interior of the heap when the fermentation is active, the liberated ammonia, in passing through the outer layers of decaying organic matter at a lower temperature, is arrested. This fact was proved by VOELKER by the analysis of fresh manure made into a heap, and left for six months. The amount of dry organic matter was found to have diminished from nine hundred and sixty pounds to six hundred and ninety; but the total amount of nitrogen at the commencement was 18.23 pounds, and at the end of six months 18.14, or nearly the same.

The practical result of these changes by fermentation is, that, weight for weight, well-rotted farmyard manure is richer in soluble fertilizing constituents than

fresh dung, and contains more readily available nitrogen, and, therefore, is more immediate and energetic in its action on vegetation.

It appears that, up to a certain point, the efficacy of farmyard manure is increased by a well-regulated fermentation, during which the loss of really valuable constituents is trifling. But there is a danger of serious loss if the fermentation is pushed too far and the manure heap is frequently turned, whilst there is great heat developed by this fermentation.

Another, and a far more serious loss, is incurred by keeping manure too long unprotected from the weather, not, however, by the volatilization of ammonia, but by the removal of salts of ammonia, soluble nitrogenized organic matters, and valuable mineral salts by rain;

well-rotted dung being more readily affected than fresh. This loss is great when the manure is kept in heaps, and the deterioration is still more rapid when the method of making manure is by animals kept in open yards. The dark-colored fluids from manure heaps, which are too frequently allowed to run into the next ditch, are but concentrated solutions of their most valuable constituents: they not only contain the valuable potassa salts and ammonia, but also phosphate of lime, a constituent brought into solution by the process of fermentation.

The following table shows the loss sustained at successive periods in twelve months, by two thousand eight hundred and thirty-eight pounds of manure put up in a heap in the usual way, and exposed to the weather:—

	When put up.			
	November 3, 1854.	April 30, 1855.	August 23, 1855.	November 15, 1855.
Weight of manure in pounds,.....	2,838	2,026	1,994	1,974
Amount of water in the manure,.....	1877·9	1336·1	1505·3	1466·5
Amount of dry matter in the manure,.....	960·1	689·9	488·7	507·5
Consisting of—				
Soluble organic matter,.....	70·38	86·51	58·83	54·04
Soluble mineral matter,.....	43·71	57·88	39·16	36·89

Management of Farmyard Manure.—The foregoing experiments teach that a certain amount of fermentation is good for farmyard manure, because it renders the fertilizing ingredients more soluble, and their effect more immediate. For the establishment and continuance of fermentation, a certain amount of heat, air, and moisture is necessary. These conditions are fulfilled when the latter is not in excess, and the excrement has been yielded by cattle fed on tolerably rich and succulent food. If the litter is in excess and but little excrementitious matter present, or not well mixed throughout with the litter, fermentation does not take place through the whole mass. Even when there is abundance of excrement, and fermentation has fully commenced, it is sometimes arrested by deficiency of moisture, and the interior of the heap presents, if no remedy is applied, a white appearance of dead, inert manure. This phenomenon is known under the name of fire-fanging. The prevention of this defect lies in the care that is taken to mix the excrement thoroughly on first collecting the manure; and if

there is a deficiency of natural moisture, in adding water from time to time. The remedy for it when present, is to turn the heap over, soak it with water, and mix it with horse-dung, or any animal offal that can be obtained. When manure has been once properly mixed and placed in heaps, which ought not to be more than three or four feet high, it should be left to itself undisturbed until carted out for use. Some farms, however, produce so large an amount of manure that it is a matter of convenience and economy to remove it during winter to the borders of the fields where it is to be applied. In these cases the manure should be stirred as little as possible when taken from its original place of deposit, and when emptied from the carts at the new heap.

The great loss to be dreaded in manure piles is, as has been seen, from the rain. The drainings from manure heaps being much more valuable than the urine of animals, it is of the utmost importance to protect the heaps from the action of rain, and to collect the fluids which escape from them, which might be

either applied as fluid manure, or, in smaller establishments, returned to the manure heaps. It might be advisable to incur the expense of covering with hurdles and straw, or with clay, such manure heaps as are placed in the fields. In these heaps the soluble salts are, in dry weather, continually brought by capillarity to the surface, only to be washed away by the next fall of rain.

Application of Farmyard Manure.—In old practice, a large dose of from thirty to fifty tons was given per acre, and not repeated till the land was nearly exhausted. The modern and improved practice is to give a moderate quantity, and repeat it often. Quantities, varying from ten to fifteen tons, are used according to the nature of the soil, the quality of the manure, and the kind of crop. It has been recommended to spread and plough it in, immediately after being deposited from the carts, on the supposition that it suffers great loss by evaporation. If the experiments of VOELKER and of WAY be correct, and there seems to be no reason to doubt their accuracy, this notion is quite false. The results of these gentlemen would seem to indicate the best mode of application to be, to spread the manure as evenly as possible on the surface of the ground, at a time when it is not saturated with moisture or bound up with frost, but in a season of frequent showers. The soluble organic and mineral matters would, in the course of ten days or a fortnight, according to the amount of rain, be washed into and retained by the soil, and the insoluble matters could then be covered up by the plough. The old method of depositing the manure on the field in heaps, and leaving it so for a length of time, is a very bad practice. The soluble matters are washed into the ground under and immediately adjoining to the heaps, and cannot afterwards be evenly distributed by rain through the soil, hence the result is irregularity in the crops of such fields.

Night-Soil and Urine.—Night-soil is in general a very rich manure, but its offensive smell has prevented it from being generally used. This exhalation may, however, be removed by various substances, such as charcoal, a charred mixture of vegetal matter and clay, *et cetera*. In the vicinity of large towns it is dried and manufactured in various ways into a portable manure, which is sold as *poudrette*, dried night-soil, *et cetera*. In China it is mixed with clay, and sold under the name of *taffo*. FORTUNE, in his wanderings in China, gives an amusing account of the extreme care exhibited by the Chinese in collecting, preparing, and applying night-soil.

BERZELIUS found the composition of fresh fæces to be—

	Centesimally.
Water,.....	73·3
Organic matter,.....	25·5
Salts,.....	1·2
	100·0

In general, human excrement contains three-fourths of its weight of water, and its composition and consequent value varies with the food, and the age and health of the individual. The following analysis of this substance by WAY shows that it contains all the fertilizing constituents necessary for different crops:—

ANALYSIS OF DRIED HUMAN FÆCES.

	Composition of the ash.	Composition of the dried excrement.
Organic matter,.....	—	88·52
Insoluble silicious matter,..	12·79	1·48
Oxide of iron,.....	4·66	0·54
Lime,.....	14·98	1·72
Magnesia,.....	13·48	1·55
Phosphoric acid,.....	37·17	4·27
Sulphuric acid,.....	2·10	0·24
Potassa,.....	10·40	1·19
Soda,.....	2·83	0·31
Chloride of sodium,.....	1·59	0·18
	100·00	100·00
Nitrogen per cent.,.....		5·00

Human Urine.—Human urine varies with the age, health, and food of the individual. It has been calculated that the average quantity voided in twenty-four hours by each member of a community is about three pounds. According to BECQUÉREL, the composition of urine in round numbers is, in a thousand parts:—

Water,.....	970·5
Solid constituents, 29·5 parts, consisting of—	
Urea,.....	13·5
Uric acid,.....	0·5
Fixed salts,.....	7·5
Organic salts,.....	8·5
	1000·0

The composition of the solid matter of evaporated urine was found by WAY to be as follows:—

	Composition of the ash.	Composition of the solid dry matter.
Organic matter and salts of ammonia,.....	—	67·54
Insoluble silicious matter,..	0·28	0·09
Oxide of iron,.....	0·14	0·05
Lime,.....	1·89	0·61
Magnesia,.....	1·49	0·47
Phosphoric acid,.....	14·31	4·66
Sulphuric acid,.....	1·43	0·46
Potassa,.....	5·64	1·83
Soda,.....	none	none
Chloride of potassium,.....	16·65	5·41
Chloride of sodium,.....	58·17	18·88
	100·00	100·00
Nitrogen per cent.,.....		19·43
Equal to ammonia,.....		23·60

When the total quantity of excrement and urine voided in twenty-four hours is taken into account, it is found that the latter is the most valuable. If the quantity of fæces for one individual for twenty-four hours be taken at one and a quarter pounds, and the quantity of urine at three pounds, the amount of nitrogen in each would be as follows:—

	Containing		
	Dry matter. Grains.	Salts. Grains.	Nitrogen. Grains.
Solid excrement voided in twenty-four hours, ..	1,750 grains— $1\frac{1}{4}$ pounds	437·5	21·0
Urine voided in twenty-four hours,.....	21,000 grains—13 pints	619·5	158·0
		26·25	125·0

These analyses show how important it is to collect and add to the manure heap the excrement of men, which, in the proportion of valuable agricultural constituents it contains, far exceeds that of other animals.

Sewage Manure.—Sewage water may be considered as consisting of the solid and liquid excrements of a town population, with all the waste materials from manufactories and private houses which rain is capable of removing. That such a liquid must necessarily possess fertilizing properties is seen by turning to the analysis of human excrement already given. But when the supply of water to each individual is taken in addition to the rain daily passing through the drains, it has been estimated by WAY that the solid matter of the urine and feces passed in twenty-four hours by one individual, is mixed with fourteen hundred times its weight of water. If only the insoluble matter of the sewage were to be separated by filtration, it would be necessary to filter nearly three thousand tons—more than half a million of gallons—to obtain from it one ton of dry manuring matter. This enormous amount of liquid constitutes the real difficulty in the way of the application of sewage liquid to agricultural purposes; still even this difficulty is simply mechanical, since it follows from LIEBIG and WAY's experiments, that, no matter how dilute a fertilizer may be, when applied, all its valuable constituents are retained by the land. The Chinese system seems to confirm the foregoing, as they prefer using their manures in a highly diluted form. Two modes of applying sewage manure have been proposed—the first, directly by irrigation; the second, by precipitating the solids and making use of them.

Where a natural fall exists for the outlet of the drains, the first plan has been most successfully carried out in various places. The rent of a meadow near Portobello, in the neighborhood of Edinburgh, was by this means raised from a few shillings to twenty-five pounds per acre. Various plans are now in agitation to carry away by a system of pipes the sewage of towns, and deliver it at a distance for agricultural purposes.

For effecting the second object—namely, the precipitation of the solids—various substances have been proposed. Among the most important of these are charcoal, lime, sulphate of lime, clays burnt and unburnt, the salts of alumina, and of zinc and iron, the compounds of magnesia, burnt magnesian lime-stone, and certain silicates. By none of these bodies are all the valuable fertilizing constituents precipitated, and many of them have little or no action at all on these substances. A good process for extracting at a moderate price the valuable constituents of sewage water is, therefore, still a desideratum.

GUANO.—**HISTORICAL NOTICE.**—This name is given to the accumulated fecal matter of sea-fowl, and is derived from the Peruvian word *huana*, signifying manure or dung. There is scarcely anything more remarkable in the history of agriculture than the introduction into Great Britain of guano as a manure. The old faith in farmyard manure was so firmly established, that the new fertilizer was received with utter distrust.

The report of its constant employment as the sole manure with the most marked success by the natives of the country from which it was imported, the results of trials with it by eminent Englishmen at home and elsewhere, obtained so little attention from the agricultural world generally, that in 1840 no greater quantity than twenty casks of it were imported. In 1841, the Earl of DERBY—then Lord STANLEY—introduced it to the notice of the public at the dinner of the Liverpool meeting of the Royal Agricultural Society of England. From this time it came rapidly into use; and, at the present moment, agriculturists have gone to the other extreme, and appear to think that they cannot get on without it. The quantities imported into Britain during the first five years after its fair introduction to agriculturists, and whilst it was slowly making its way with them, compared with the importations of the last five years, will show how enormously this substance has risen in repute:—

	Tons.		Tons.
1841,.....	1,733	1853,.....	123,166
1842,.....	13,094	1854,.....	235,111
1843,.....	4,056	1855,.....	143,136
1844,.....	81,902	1856,.....	191,501
1845,.....	220,914	1857,.....	288,362

The deposits of guano longest known, and for some time supposed to be the only ones, are those on the islands and sea-boards of Peru, between the thirteenth and twenty-first degrees of South latitude. The Peruvians are known to have made use of this substance as a fertilizer from the twelfth century. Their soil, which consists of sand and clay, and is naturally most barren, was enabled by the use of guano to produce year after year abundant crops of grain.

The Chincha Islands, which afford the best guano, are, according to Dr. URE, three in number, and lie in one line from North to South, about half a mile apart. Each island is from five to six miles in circumference, and consists of granite covered with guano, in some places to a height of two hundred feet, in successive horizontal layers, each layer being from three feet to ten inches in thickness, and varying in color from light to dark-brown. No earthy matter whatsoever is mixed with this mass of excrements. In some of these islands, however, the deposit does not exceed three to four feet in thickness. The total quantity of guano estimated to be on these islands by M'INTOSH, in his report to the Admiralty, was eight million six hundred thousand tons. According to the Peruvian survey, the quantity is double of this—namely, eighteen million two hundred and fifty thousand tons. Dr. KINAHAN, in his paper in the Journal of the Royal Dublin Society for July, 1856, gives fifteen to twenty million tons; whilst others estimate it so high as from one hundred to one hundred and fifty million tons. From a rough estimate made by Mr. WALTON, it would appear that the deposit of guano in Peru continues by the yearly addition of a fresh quantity of excrement amounting to about thirty thousand tons, which, however, does not all become available. Since the demand for guano has so increased, other localities have been searched, and supplies have been obtained from other and widely-separated regions. The coasts of Chili, Bolivia, Patagonia,

Cuba, Labrador, Australia, and the isles of Ichaboe, Malaya, Augra, Peguena, and near the Cape of Good Hope, and of Kooria Moorla, near the coast of Arabia, have furnished supplies of greater or less magnitude, and of very varying qualities. It is highly probable that deposits of this substance will be found in every region much frequented by sea-fowl, and that further stores will yet be opened up when closer investigations have been made of the many uninhabited islands of the Pacific Ocean.

Fertilizing Power of Guano.—Guano owes its fertilizing power to its being a well-tempered mixture of nearly all the essential ingredients necessary for the nourishment of all cultivated crops. Its properties are particularly due to the large quantity of phosphates and ammonia which it contains, and these in a concentrated form. In the best guano—such as the Peruvian—there is present a considerable portion of alkaline phosphates, so that in itself guano combines all the good properties possessed by different manures separately. It contains soluble phosphates and salts of ammonia ready to be at once carried in solution in water into the roots of plants, and a further supply of these substances in a less soluble form, but which, by the aid of decomposition, and by the carbonic acid of the soil, are gradually dissolved and made available in proportion to the wants of the growing plant. There is only required the soluble silicates so necessary to the stems of the cereals, and which must be derived from some other source.

If the value of a manure be calculated, as is done by BOUSSINGAULT, according to the amount of nitrogen it contains, NESBIT estimates that one ton of good Peruvian guano is equal to

33½ tons of farmyard manure.
21 tons of horse dung.
35½ tons of cow dung.
22½ tons of pig dung.
14½ tons of mixed human excrements.

From the form in which the mineral constituents exist in guano, it is a manure peculiarly fitted for application in known quantities to the immediate wants of the growing crop.

It is not intended to convey by this, that the amount of mineral constituents to be removed by a given crop is to be calculated, and the exact corresponding amount of mineral matter in the guano to be added. As the roots of the growing crop are not likely to find *all* the substances added to the soil, a considerably greater quantity of mineral matter is actually employed than is likely to be removed by the crop. With this allowance the agriculturist is able to regulate his supply to the demand of the crop, and to go to no greater expense than what he may deem necessary for the existing wants. The materials are in a form in which they can be dissolved and made use of by the one growing crop; and if only added to the land in sufficient quantity for that one crop, no effect can be looked for in the succeeding crop.

The quantity of guano usually applied per acre varies from two to five hundredweight. It is applied directly as a top-dressing, spread broad-cast by hand over the surface, or in compost with other substances, either

broad-cast or in drills, and buried by the plough. From its caustic nature, guano should not be placed in contact with the seed. In the case of wheat it may be sown broad-cast over the young plants in wet weather, and then harrowed in. With grass, clover, and such seeds sown broad-cast, it may be applied ten days before the seed, the land being immediately harrowed and allowed to absorb the manure. For turnips and other drilled crops, when used as an auxiliary to farm manure, it has been recommended to be sown broad-cast over the drills before they are split by the plough, to cover the farmyard manure in the furrows; the guano is thus mingled above the manure with the earth in which the turnip seed is to germinate. Perhaps, as has been recommended by NESBIT, it would be preferable to apply two-thirds of the guano broad-cast and one-third in drill with the seed. For this purpose the guano must be mixed with four to six times its weight of the ashes of wood or peat charcoal. The guano and ashes are then mixed in alternate layers by the spade or a sieve, and, after being well turned and mixed, left for eight days, and, finally, thoroughly incorporated by sifting; it is then fit for use. Great care must be taken that, in the drill, this mixture fall below the seed, and that the latter be protected by the intervention of an inch or two of soil.

Analysis of Guano.—Guano is a very complex mixture, containing urate, oxalate, and phosphate of ammonia, earthy phosphates, soluble alkaline salts, and organic matter. The analysis of such a compound is attended with some labor. As the value of guanos, however, depends on the quantity of ammonia, phosphates, soluble and insoluble, and alkaline salts which they contain, a very simple analysis is quite sufficient for agricultural purposes.

The guanos brought from different localities may be ranged under two heads—the ammoniacal and the phosphatic. The Peruvian is the type of the former, and is valuable for the large quantity of ammonia which it eviscerates. The Bolivian or Saldanha Bay may be taken as the type of the phosphatic class, which contains a small proportion of ammonia, with large quantities of earthy phosphates.

The composition of the different kinds of guano more generally imported, is the following:—

The composition of the Peruvian is the average of seventy-eight analyses made by WAY.

COMPOSITION OF PERUVIAN GUANO.

	Centesimally.
Moisture,	13·67
Organic matter and salts of ammonia,	52·05
Earthy phosphates,	22·78
Alkaline salts containing 3·34 phosphoric acid, and equal to 6·89 soluble phosphate of lime,	9·67
Sand, <i>et cetera</i> ,	1·83
	<hr/> 100·00
Ammonia per cent.,	16·52

A variety of Peruvian guano, under the name of Augamos guano, is also met with in the market. It is the freshly-deposited faecal matter of birds, is richer than Peruvian guano in ammonia, and brings a higher

price. Only a few cargoes of this substance are annually obtainable. Its composition is subjoined:—

	Centesimally.
Moisture,.....	10·5
Organic matter and salts of ammonia,.....	62·5
Earthy phosphates,.....	17·0
Alkaline salts,.....	7·5
Sand, <i>et cetera</i> ,	5·2
	100·0
Ammonia per cent.,	21·1

The following is a simple method for analysing guano, which gives sufficiently accurate results for commercial and agricultural purposes. The sample of guano, which ought to be taken from different bags, is to be well mixed, and about two pounds of this taken for analysis. If there are lumps in the sample, these are to be finely pounded, and the whole repeatedly passed through a sieve so as to get a uniform mixture. To determine the moisture, about fifty grains are to be dried at 212° till they cease to lose weight.

For Ammonia.—If the sample is rich in ammonia, about twenty grains, and, if poor, about fifty grains are taken, a few drops of hydrochloric acid added to prevent the loss of this alkali, which takes place in some guanos on exsiccation, and then dried at 212°, and burnt with soda-lime, which must also be previously desiccated and cooled immediately before use. The mixture is introduced as rapidly as possible into the combustion tube. No appreciable loss of ammonia occurs if the substances are well dried before mixing. For ordinary purposes, sufficiently exact results are obtained by simply evaporating the chloride of ammonium on a water bath to dryness. One part of this salt represents 0·315 of ammonia.

Fifty grains of the sample are burned at not too high a temperature, till they cease to lose weight. The loss in weight represents the moisture, organic matter, and ammoniacal salts.

After being weighed, the ash is digested in warm water, filtered, and washed two or three times. The residue, dried and weighed, represents matters insoluble in water; the loss represents the soluble alkaline salts, which generally consist of chlorides and sulphates; and in the case of the better class of guanos, such as Peruvian, also of alkaline phosphates. The aqueous filtrate may be divided into two portions, in one of which the phosphoric acid is determined by the addition of sulphate of magnesia, ammonia, and chloride of ammonium. One hundred parts of the precipitate, dried, ignited, and weighed, contain 64·30 parts of phosphoric acid. It will be sufficient to evaporate almost to dryness about one ounce of the second por-

tion of the fluid, and to test for the presence of potassa, soda, sulphuric acid, and chlorine.

The ash left by the water is treated with dilute hydrochloric acid, filtered, and the residue washed and weighed. The undissolved portion is sand, clay, and, in recent or adulterated guanos, gypsum. By boiling the residue for half an hour in a concentrated solution of carbonate of soda, filtering, washing the residue, and then acting on it in the filter with dilute hydrochloric acid, and again washing, the gypsum will be tolerably well removed from the sand and clay. The difference in weight represents the sulphate of lime. If gypsum is present, the portion of this dissolved in the watery solution is apt to be reckoned as soluble alkaline salts: correction should be made for this.

The hydrochloric-acid solution is precipitated by ammonia, and the earthy phosphates filtered, dried, and weighed. The precipitate obtained by ammonia when added to the sand and gypsum, ought to be nearly the same as the weight of ash left by the water. When this is not the case it is due to impurities, such as carbonate of lime, and the loss of weight corresponds to the quantity of this substance present.

Adulterations of Guano.—From its high price there is no manure so subject to adulterations as guano. The substances generally made use of for this purpose are sand, marl, limestone, clay, powdered bricks or tiles, gypsum, chloride of sodium, *et cetera*. One or more of these substances mixed with the strong smelling guanos, such as the Ichaboe, and by the addition of a few feathers, form altogether so prime-looking an article, that even experienced buyers are deceived by it. Chemical analysis alone can reveal the deception.

Various simple experiments have been proposed to enable inexperienced unscientific persons to say whether a given sample of guano is or is not sophisticated. The conclusions are drawn from the specific gravity, the color of the ash, effervescence with an acid, *et cetera*. But such conclusions would only be correct for certain specimens of guano—not for all.

The following are simple means by which adulterations of genuine Peruvian guano can be detected.

When burnt it leaves a perfectly white ash, when pure; but if adulterated with sand, marl, *et cetera*, the ash is more or less of a brown, or reddish-brown color. On the addition of strong acetic acid or hydrochloric acid to the ash, there is no effervescence if pure, but strong effervescence if adulterated with marl or chalk.

On the Mode of Estimating the Money Value of Guano.—If the money value of a manure is to be calculated, it is only necessary to ascertain the prices at which its valuable ingredients can be purchased in the market. Agricultural chemists have endeavored to fix the market value of the different constituents of manures, but their scales are not uniform. The following table gives the value per ton of the different constituents of manures, according to four different agricultural chemists:—

	Way.			Hodges.		
Ammonia,	£56	0	0	£56	0	0
Insoluble phosphates, ..	7	0	0	7	0	0
Soluble phosphates,	32	13	0	25	0	0
Potassa,	30	16	0	20	0	0
Alkaline salts,	1	0	0	1	0	0
Organic matters,	1	0	0	0	10	0
Gypsum,	0	0	0	0	0	0

	Nesbit.			Anderson.		
Ammonia,	£60	0	0	£56	0	0
Insoluble phosphates, ..	8	0	0	7	0	0
Soluble phosphates,	24	0	0	28	0	0
Potassa,	0	0	0	20	0	0
Alkaline salts,	1	0	0	1	0	0
Organic matters,	1	0	0	0	0	0
Gypsum,	1	0	0	0	0	0

Discarding the decimals below 0·5, reckoning those above 0·5 as an additional unit, and leaving out of the calculation the value of the organic matter and potassa, the price of Peruvian guano would be the following, supposing the market value of its constituents to be as above stated according to WAY:—

	Value per ton.			Total.
Moisture,	13·67	—
Organic matter,	52·05	—
Earthy phosphates,	23·0	£7 0 0	£161
Soluble phosphates,	7·0	32 13 0	228
Alkaline salts,	10·0	1 0 0	10
Potassa and the al- kalies,	3·0	30 0 0	90
Ammonia,	16·50	56 0 0	924

SPECIAL MANURES.—*Bone Manure History.*—Bone manure is said to have been long in use in hothouses in Germany, whence it was first introduced into England. ARTHUR YOUNG in his Northern Tour, 1770, mentions, that in the neighborhood of Sheffield bones were a very common manure for grass. About the same period, bones were used for turnips and arable crops in the limestone district of Yorkshire, and Lincolnshire. Like guano, it was at first received with distrust, and only after many years took its place in agriculture as one of the most valuable special manures known. In 1823, the declared value of bones imported into Great Britain was only fourteen thousand three hundred and ninety-five pounds sterling, and in 1837, it was two hundred and fifty-four thousand six hundred pounds sterling. In 1815, the quantity imported into Hull was about eight thousand tons, in 1833, it was seventeen thousand five hundred tons, and in 1835, was twenty-five thousand seven hundred tons. The chief supply comes from Germany and Russia,

and from the coasts of the Baltic. The earlier form of using this manure was as calcined bones, or when uncalcined, they were broken in pieces and distributed at the bottom of the manure heap, to undergo decomposition. In 1840, an increased impetus was given to the employment of bones, by the recommendation of LIEBIG to render it more readily soluble and available to plants by the action of sulphuric acid.

Theory of the Action of Bones.—Bones consist of two portions, organic and inorganic, in the proportion of about thirty-three of the former, to sixty-seven of the latter. The chief portion of the inorganic part, the phosphate of lime, called in agricultural language, bone earth, is supposed by BERZELIUS, to be a peculiar basic compound of eight equivalents of lime, united to three of phosphoric acid, and having the following per centage composition:—

	Centesimally.
Lime,	51·12
Phosphoric acid,	48·88
	100·00

MITSCHERLICH and others, however, regard it with more probability as a compound of three equivalents of lime and one of phosphoric acid, its composition being

	Centesimally.
Lime,	53·86
Phosphoric acid,	46·14
	100·00

The thirty-three per cent. of organic matter yield, by decay, about five and a half per cent. of ammonia. Hence fresh bones are valuable as a manure for the large quantity of earthy phosphates they contain, and the considerable amount of ammonia they are capable of yielding.

LIEBIG's axiom is, that no special manure can be of any use if the soil does not possess the other ingredients necessary to the crop. Bones are, therefore, only valuable when these conditions are fulfilled. Under such circumstances they have been proved to be the manure for turnips.

As bones furnish only two substances to crops, science as well as experience indicates that they are more likely to be useful when used as auxiliaries—for example, with farmyard manure, *et cetera*. At all events, that this is true, when bones are to be used for some years, may be deduced from the mineral theory. A striking instance of this fact occurred in Nottinghamshire. The soil was supposed to have become deficient in bone earth, and as the first applications produced very good results, it was supposed that by the constant repetition of a larger quantity increased fertility would follow. These hopes were disappointed, until it was shown by other experiments that other mineral constituents were necessary. By the addition of these, the accumulated stores of dormant bone earth immediately began to develop wonderful effects. This is but another instance of the truth of the mineral theory of LIEBIG.

The rapid fertilizing effects of bones depend on the state in which they are presented to the roots of plants. When buried in the entire state, they undergo decomposition very slowly. Hence it has been found neces-

sary to make them more rapidly available by grinding them, in which state they undergo fermentation readily, are reduced to powder, and thus made more soluble; or the ground bones, instead of being allowed to ferment, are first acted on by sulphuric acid, by which they are converted into a soluble form, known under the name of superphosphate.

Steamed Bones.—Mr. BLACKALL found, that bones submitted to high-pressure steam decomposed rapidly in the soil. This method was recommended by him as a good process for agricultural purposes. Others have found it necessary to crush the bones after steaming, to render them fit for application. In this method there is a loss of nitrogen in the gelatin dissolved out by the steam.

Fermented Bones.—Another mode for the decomposition of bones, so as to render them more readily available, is by fermentation. The process consists in mixing the bones with earth, ashes, farmyard manure into a compost, and leaving them to ferment. Certain substances, such as peat-ashes, have been supposed to cause this action more rapidly. Mr. PUSEY showed in 1847, that by mixing bones with an inert substance, such as sand, and watering the heap, and then closely covering up the whole with earth, putrefactive fermentation was generated.

The process would be still more effectual, and produce a better mixture, if instead of sand, wood or peat ashes were added to the ground bones, and urine employed to moisten the mass instead of water. As there might be a loss of ammonia by the heat generated, it would be advisable to spread a layer of sulphate of lime between the bones and the covering of clay; or to mix two or three hundredweight of gypsum with every ton of bones.

Dissolved Bones.—*Superphosphate of Lime.*—This term is bestowed on the commercial mixture of bones and sulphuric acid rendered dry by various absorbents. The mixture consists essentially of neutral phosphate of lime, which is scarcely soluble in water; biphosphate of lime, which is quite soluble; and sulphate of lime.

If the composition of the neutral phosphate of lime be taken according to BERZELIUS, as

Phosphoric acid,	48.5
Lime,	51.5
	100.0

and the biphosphate, as containing

Phosphoric acid,	71.5
Lime,	28.5
	100.0

Then one hundred parts of neutral phosphate can be converted into sixty-eight parts of biphosphate by the removal of thirty-two parts of lime by sulphuric acid. But as the materials from which superphosphate is manufactured, namely, bones, coprolites, *et cetera*, are not pure neutral phosphates of lime, a larger quantity of sulphuric acid is required. The average composition of raw bones may be taken as the following:—

Water, fat, and cartilage,	48
Phosphate of lime, with a little phosphate of magnesia,	46
Carbonate of lime,	4
Alkaline chlorides and sulphates,	2
	100

If the whole of this is to be converted into biphosphate, the following quantities of sulphuric acid, of specific gravity 1.70, would be required:—

	Pounds.
To neutralize the carbonate,	4
To convert the whole phosphate into biphos- phate	25
Total,	29

Provided the bones are finely ground, and the acid and crushed bones well mixed, theory would indicate that, by employing sulphuric acid to the extent of one-third of the weight of the raw bones, the whole of the bones would be converted into biphosphate.

Superphosphate of Lime from Coprolites.—Coprolites have been extensively used as a substitute for bones in the manufacture of superphosphates, but they do not produce so good an article. They are very hard, and unless well ground, which is frequently not the case, they are not readily acted on by acid; moreover, a larger quantity of acid is also necessary, as they contain a larger proportion of carbonate of lime.

Practical Rules for the Manufacture of Superphosphate of Lime.—The essential condition in this manufacture is, to reduce the bones or coprolites to be acted upon to as fine a state as possible before applying the acid. The sulphuric acid, mixed with twice its bulk of water, or further diluted with due regard to the subsequent drying, is added by degrees to the crushed materials, which are kept constantly stirred so as to bring all parts into contact with the acid. The absorbents, which are either ashes, mould, bones, coprolites, or some such materials, are then to be added, till the mass is sufficiently dry. Where machinery cannot be had, the following modification of a plan proposed by Mr. PUSEY has been found useful, on a small scale, for the conversion of eighty bushels of bones. A circular wall, in height about two feet, is formed of ashes. The space inclosed is about ten feet. The crushed bones are passed through a fine quarter-inch sieve. The coarser particles are laid flat in the centre, and the finer are placed round the ring, close to the ashes. Water is then added to the bones so as thoroughly to saturate them, after which they are turned over frequently in the course of a few hours. If a sufficient quantity of water has been added to the bones, it is not necessary to dilute the acid any further. If one part, by measure, of acid is to be used with three parts of water, it is better to use one-half of this water to saturate the bones, and to dilute the acid with the other half of the water. After the bones have been turned the acid is added gradually, the bones being constantly turned and mixed with the spade. In six or eight hours after the addition of the acid, the fine bone-dust, forming the second circle, is thoroughly mixed with the bulk. Next day the ashes forming the outer wall are thrown over the heap, which is then left undisturbed for a week. The heap is then opened out and thoroughly mixed with the ashes, and finally passed through a sieve. If not sufficiently dry for this last operation, a further quantity of ashes may be added to it.

Composition of Superphosphate of Lime.—It is extremely difficult to give the average composition of superphosphate of lime, which might serve as a standard

of comparison for this substance, as Peruvian guano does for manures of that class. This arises from the difference in the materials, and in the mode of manufacture.

According to theory, if one hundred pounds of raw bones could be perfectly acted on by twenty-nine pounds of strong sulphuric acid, the composition of the resulting superphosphate would be in round numbers—

Moisture,.....	10	
Animal matter and fat,.....	27	
Sulphate of lime,.....	39	
Biphosphate of lime,.....	24	{ = to 35 parts of bone earth phosphate rendered soluble.
	100	

The animal matter, about twenty-one per cent., would furnish about one and a half pounds of ammonia. It is, however, practically impossible with these quantities to convert the bones as completely as stated above, into superphosphate.

Of one hundred and seventy-one samples analysed by WAY, he found

	Per cent. of soluble phosphates.
11 samples containing.....	5
49 " " between.....	5 and 10
60 " " ".....	10 and 15
40 " " ".....	15 and 20
11 " " over.....	20

From these analyses he concludes, that a good superphosphate will contain between ten and twenty per cent. of soluble phosphate; that is to say, the biphosphate is calculated so as to represent neutral phosphate, which is thus represented as soluble. In round numbers, twenty-four parts of biphosphate are equivalent to thirty-five parts of bone-earth phosphate rendered soluble.

ANDERSON, WAY, and the Editor, from numerous analyses, have adopted fifteen per cent. as the average amount of soluble and the same of insoluble phosphate in the above article as vended. With these data, the average composition of superphosphate in the market in 1856 was

Moisture,.....	10	
Animal matter,.....	27	
Biphosphate of lime,.....	10	{ = to 15 per cent. of soluble bone earth.
Insoluble phosphate of lime,.....	15	
Hydrated gypsum,.....	34	
Alkaline salts,.....	4	
	100	
Ammonia, about 1·5 per cent.		

The money value of this superphosphate, calculated according to the plan adopted for guano, after leaving out the non-essentials, would be as follows:—

	Per ton.
Soluble phosphate of lime,.....	15 × £33 = £495
Insoluble phosphate of lime,.....	15 × 7 = 105
Gypsum,.....	34 × 1 = 34
Alkaline salts,.....	4 × 1 = 4
Ammonia,.....	1·5 × 56 = 84
	£722

Price about seven pounds five shillings per ton.

According to the opinion of some agricultural chemists, the manufacture of superphosphate of lime will be imperfect so long as insoluble phosphate figures as one of

its ingredients. Manufacturers now send superior articles into the market, and many samples of superphosphates are found in which no insoluble phosphates exist, and the proportion of the soluble phosphates is considerably above twenty per cent.

Analysis, Adulteration, et cetera, of Superphosphates.

—The analysing of superphosphate of lime is substantially the same as for guano. The determination of phosphoric acid in the soluble phosphates may be rapidly and conveniently made in the following manner: A considerable quantity, say a quarter of an ounce is taken and mixed with about four ounces, by measure, of hot water, and allowed to settle, and the supernatant fluid poured through a filter. The residue is treated in the same way, two or three times, with a fresh portion of water. About a quarter portion of this fluid is taken for analysis, neutralized with ammonia, and again rendered acid by acetic acid; and after the addition of acetate of potassa or ammonia, the phosphoric acid is precipitated by the addition from an alkalimeter of a solution of sesquichloride of iron of known strength. After being rapidly filtered, and washed with hot water and dried, the increase in weight over the known quantity of sesquioxide of iron added, represents the phosphoric acid, 48·5 of which correspond to one hundred parts of bone-earth phosphate rendered soluble, and 71·5 to one hundred of biphosphate of lime.

Application of Bone Manure.—As a manure for grain crops, bones are not in repute. Their addition, however, is of use on those soils, such as peats, in which phosphates are deficient. It is almost exclusively in the light of a turnip manure that bones hold their high place in agriculture. The mode of using superphosphate of lime is either in solution or in compost. The former is the more effectual method, but it is attended with more expense and inconvenience; hence the latter is the plan generally adopted. It is applied in drills with the seed. The quantity employed should vary with the circumstances of the soil, and with the quality of the manure. About five hundredweight per acre is an average quantity.

The remaining special manures may be regarded as divided into the nitrogenous, or those employed for their nitrogen; and the mineral, or those taken for the bases they contain.

The nitrogenous manures of vegetal and animal nature, such as wool, horns, and the like, are slow in their action. They undergo decomposition very gradually in the soil, with the liberation of ammonia; hence they are but of little value when an immediate effect is required. Recourse must then be had to a salt of ammonia, or nitrate of potassa or soda.

When the various points discussed in the preceding pages are borne in mind, it cannot but excite surprise to see, on the one hand, the loss sustained by old and long-known manures from utter unacquaintance with their really valuable ingredients; and, on the other, to notice how many sources are at present neglected, from which fertilizing agents, either general or special, might be obtained. The dire necessity of augmenting the production of the soil in proportion to the increase of the population, has compelled practical

agriculturists to call in the aid of science. The few years in which science and practice have been united have already effected the solution of many contradictory and crude opinions, based on blind empiricism, by showing wherein really consisted the value of manures, and the proper mode of treating them, so as to obtain their maximum fertilizing effects, and by directing attention, on well-grounded principles, to many hitherto-neglected sources of manures. The old struggle still continues between blind practice and the new views. The energy of the numerous scientific men who now devote their talents to agricultural chemistry leads, however, to the hope that, in a few years more, the laws which govern the proper tillage of the ground will be more thoroughly investigated and understood; agriculture will then take its stand as a more exact science than at present, and the cultivation of crops can then be entered upon as an art with as much certainty as any other manufacture.

ARTIFICIAL MANURES.—Twenty-five years ago, when the manufacture of spa and mineral waters began, they met with violent opposition from the members of the faculty, as being deprived of all the good qualities of the natural ones—as wanting, in a certain *conditio, sine qua non*—in a *spiritus rector*, or vital power, which alone gave them any medicinal qualities. Those times have passed now; chemistry has demonstrated to a certainty what the constituents of those various waters are, and under what forms and compounds they are united in them. It has succeeded in combining them exactly in the same proportions, and in rendering them not only equal to the natural ones, but *even more effective*. Physicians now connect certain effects on the human body with certain elements in the waters, and are enabled, by the light of science, to add more of this element, or more of that; nay, to apply, instead of the waters themselves, the one active element alone, as is, for instance, the case with iodine in indurations and struma. It is well known that at this moment there are extensive manufactories of mineral waters in England, at Berlin, at Dresden, at Vienna, *et cetera*. The mineral waters which are manufactured by the Messrs. ELLIS at Ruthin, in North Wales, and by a few other firms, are in every respect equal, if not superior, to the natural ones. Now, the Editor believes that the same principle may be applied, partially at least, to the use of manufactured manures; and, in fact, this is proved by the success that has attended the application of several. To dwell at large upon all the artificial manures that are now manufactured in hundreds and thousands of tons annually, would occupy more space than is at the Editor's command; he will, therefore, only append the analyses of those which have come under his immediate notice, and which have been eagerly sought after by the agriculturist. The recipes may be improved, no doubt, still the manufacturers of artificial manures may profit by studying the various per centages of the different constituents in each. Three of the best have been selected out of the numerous samples that have been analysed by the Editor. No. 1 is a manure manufactured by Messrs. KNIGHT and Company, Widnes, near Warrington, an inspection of whose works will prove

interesting to the agriculturist. No. 2 is made by the British Patent Manure Company in Manchester; and No. 3 is produced at the Runcorn Bone Works. Most satisfactory results have been obtained wherever the composts have had a fair trial:—

In concluding this article, the Editor feels great pleasure in expressing his thanks to his talented friend, Dr. BLYTH of the Queen's College, Cork, for much valuable matter that he has supplied during its compilation. The Editor could not have had a more competent contributor, for Professor BLYTH was for many years the agricultural chemist at the college of Ciren-
cester, where daily, under his inspection, were carried out experimental researches on the different kinds of manures.

MERCURY.—*Mercure*, French; *Quecksilber*, German; *Hydrargyrum*, Latin.—Mercury is a substance which has only of late been raised to the dignity of a metal, notwithstanding its being known long before the Christian era, and extensively experimented upon, more especially whilst the powerful idea of transmutation, and of the *elixir vitæ*, possessed the minds of the first chemical students—the alchemists. Its characteristics are very marked, and in one respect different from any other known metal, namely, its fluidity at all ordinary temperatures. It was this property, coupled with its silvery whiteness and metallic lustre, which determined its other popular name, quicksilver. Though it is not spoken of in the ancient scriptural writings, still THOMSON in his *History of Chemistry*, states, that its discovery must have preceded the earliest historical records. It was common in the time of MOSES; for, according to Dr. HERBERT, the Egyptian magi employed it in their so called *enchantments*, when every man cast down his rod and it became a serpent. ARISTOTLE relates, that DÆDALUS gave motion to a wooden Venus, by means of a current of mercury. DIOSCORIDES describes a method for its reduction from cinnabar, or *minium*, as it was then designated, and which is remarkable as being the first record of a process that led to distillation. The metal in those times was employed in gilding, much in the same way as at present, and the minium or cinnabar had its application in painting and decoration. PLINY mentions that CALLIAS, an Athenian, was acquainted with the preparation of the mercuric sulphide. The Greeks converted considerable quantities of the latter compound to this use, and were in the habit of drawing their supply from Spain, the mines of which were known and worked seven hundred years before the Christian era. In latter times the virtues of the sulphide as a medicine was established, and this, as well as the metal, was extensively administered by the professors of the healing art.

DIOSCORIDES, who cites some of the properties of the metal, had, it is evident, but an imperfect knowledge of it; for he states, that it could be retained in vessels of glass, tin, lead, or silver—an assertion which is now well known to be untrue, especially with regard to the metals that he named. PLINY also seems undecided as to its true nature, since evidently he thought that there was some radical difference between the mercury which was found in the virgin state and that obtained by the manufacture of the time. The former was known as quicksilver—*argentum-vivum*—and the latter as mercury—*hydrargyrum*. This doubt lurked in the minds of even the learned alchemists and philosophers till towards the close of the seventeenth century, when both kinds were submitted to numerous distillations—as in the case of BOERHAAVE, who distilled the same portion of mercury successively five hundred times, and the products were found to coincide in weight and all the then known properties. Still, at this period, owing to its fluidity especially, it was regarded as an imperfect or semi-metal, containing a principle regarded as pure vitrifiable earth—the silica of modern time. The fact of this terrestrial principle conferring solidity upon such bodies as contain it in abundance, being directly opposed to the fluid condition of mercury, induced BECCHER, an investigator of the first half of the seventeenth century, to admit the existence of another principle, a *mercurial earth*, which was supposed to possess weight and volatility to a very great degree. This chemist regarded quicksilver as a compound of three substances—namely, the vitrifiable, the inflammable or phlogistic, and the mercurial. He was supported in his views by STAHL and other learned semi-alchemists, till by the introduction of a course of experimental research and deductions, the nature of bodies came to be regarded in a simpler but truer light, which overthrew the hypothetical obscurity that pervaded all chemistry up till that time.

The knowledge that it could be solidified, acquired by the academicians of Petersburg in 1759, was the first means to remove the notion of its semi-metallic nature, and inquiries to which the announcement of the fact gave rise in the hands of PALLAS, HUTCHINS, BIEKER, BLAGDEN, and several others, led the way to its recognition as a true metal, and elementary body.

PREPARATION.—Several methods are known for the production of mercury from its saline combinations, many of which are practised on the large scale, and will consequently be described when treating of its smelting, but as these do not yield a pure metal, reference will be here made only to the methods that are calculated to afford such a product.

The mercury of commerce, which usually is contaminated with variable portions of lead, tin, and bismuth, may be distilled with one-tenth of its weight of cinnabar; and provided the distillation be carefully effected, the foreign impurities will be found in the retort, in the form of sulphides, after the pure mercury has passed over into the receiver. A purer product is, however, obtained when carefully prepared cinnabar or corrosive sublimate—chloride of mercury—that has been cautiously sublimed, is distilled with one part of quicklime or iron filings. The principal part of the impu-

rities is removed in the formation and sublimation of the sulphide or chloride taken, and the last traces are retained, with the sulphide of calcium, or iron, generated in the second part of the process. Sometimes agitation with concentrated nitric or sulphuric acids has the effect of rendering mercury much purer, but, in any case, can the product obtained by the process described be excelled. To ascertain its purity, it is only necessary to dissolve a portion in an excess of nitric acid, evaporate the solution, and heat the dry salt to redness; or fuse the metal with pure sulphur, and sublime the product in a glass matrass; in either case nothing should remain if the metal be pure, but if a residue appear, the impurities are proportionate to its weight. Observation has led to the adoption of a simpler, but less reliable test than the above; it is this, that pure mercury when dropped upon a smooth, but slightly-inclined surface, breaks up into drops which retain the spherical form, but if contaminated with tin, lead, or such adulterants or impurities, the form of the globules will appear elongated, so as to present or leave a *tail*.

PROPERTIES.—Mercury is a metal that possesses the metallic lustre in a high degree, and exhibits a silvery whiteness. It is fluid at all temperatures between 39.5° Fahr., and its boiling point, which is variously estimated by different experimenters, as ranging between 654.8° CHRICHTON; and 680° DULONG and PETIT—DALTON estimating it at 660.2°; and HEINRICH at 672.8°. At minus 40° it solidifies, and while in this state permits of being beaten out under the hammer, welded, *et cetera*, like other metals. When the refrigeration is effected by means of solid carbonic acid and ether in a dish, and if the yet unsolidified portion be poured off, the metal adhering to the walls of the vessel will present well defined octahedral crystals. Its density varies with the degree of temperature more than any other metal, owing to the freedom with which it expands. SCHULZE found it in the solid state to be 14.391. REGNAULT estimated the gravity at — 40° to be 14.4, but if it could be compressed by hammering, the number would doubtless be higher. At 39.2° KOPP estimated its gravity at 13.594; KUPFER at 13.588, and 13.535 at 78.8°; at the latter degree the number arrived at by CAVENDISH and BRISSON was 13.568; by FAHRENHEIT 13.757. KARSTEN determined its density at the ordinary temperature to be 13.559. Various researches show that this metal evaporates at common temperatures, as well in contact with air as *in vacuo*. This may be proved by suspending gold leaf in a flask containing some of the metal, when, after a few weeks, the lower portion of the leaf will appear amalgamated. KARSTEN asserts that at 32° mercury gives off as much vapor as to develop the image on a daguerreotype plate held over it at a convenient distance. BRAME affirms that sulphur in a finely-divided condition, as when precipitated from a state of vapor, is much more delicate than gold leaf. By its aid he found that at 53.6°, the tension of the vapor rises to the height of three feet, and even higher than this; but, in the latter case, the delicacy of the known tests is inadequate for its detection. This investigator is also of opinion that in air and vapor of sulphur, the vapor of mercury diffuses itself according to the law which governs other gases.

The specific gravity of the vapor of mercury was found by DUMAS to be 6.976, and by MITSCHERLICH 7.03—the latter number being that arrived at by theory. The property of expansion which mercury possesses, and the long range of temperature through which it exhibits this property with remarkable regularity, render it peculiarly adapted to the wants of the philosopher for determining the sensible heat of bodies. Repeated experiments have shown, that between 32° and 212°, the increase of bulk which it acquires, by the acquisition of equal increments of heat, is extremely regular, and corresponds to 0.00011 of its bulk at 32°, according to the experiments of DALTON. Between 38° below zero—the lowest degree of temperature that can be safely estimated by the mercurial thermometer—and + 32°, the freezing point of water, the gradation is not so regular, although the difference is so trifling as to be disregarded in most applications; but between 212° and 662°, it has been found to pass from the regular expansion observed between the limits of the freezing and boiling points of water, and to increase in this respect as the heat becomes more elevated. The annexed table exhibits the ratio of expansion of mercury between 32° and 212°, as determined by the investigators mentioned:—

•0200	Dalton.
•01887	Cavendish.
•01848	Lavoisier and Laplace.
•01818	Hallstrom.
•01801	Shuchburgh.
•01800	Dulong and Petit.
•01781	Deluc.
•01695	Roy.
•018153	Militzer and Regnault.

The following numbers, arrived at by DULONG and PETIT, show the variable and increased expansion of mercury above air by equal increments of heat:—

COMPARATIVE EXPANSION OF AIR AND MERCURY BY THE SAME INCREMENTS OF HEAT.

Dulong and Petit.		Rudberg.	
Air.	Mercury.	Air.	Mercury.
0°	0°	35.96	36°
100°	100.0	0°	0°
150°	151.3	+ 50.04	+ 50°
200°	204.6	100°	100°
250°	255.1	198.81	200°
300°	314.15	294.73	300°
350°	360.00	—	—

Mercury is not acted upon when exposed to air, oxygen, nitrogen, nitrous or nitric oxide, or carbonic acid gases. On the contrary, if shaken with water, ether, oil of turpentine, or fatty unctuous matters, it loses its metallic appearance, and is converted into a grey *æthiops per se*, in which the metal is not altered but *deadened*—that is, reduced to minute and isolated globules by the interposed stratum of the compounded matter. Ordinary mercurial ointments retain the metal in this state, but so finely divided as to render its detection by the unaided sight impossible. When pure it is tasteless and inodorous, although a peculiar odor has been observed from it when rubbed between the fingers. Poured upon dry bodies, it does not wet them like other liquids, but flows off in drops, except in the case of the metals with which it forms amalgams. On this account it is designated, sometimes, in old writings, *aqua non*

ma defaciens manus—water that does not wet the hands. Kept at a temperature approaching ebullition in contact with air, it suffers oxidation slowly. Water is not decomposed by it. The nitrous, nitric, iodic, chloric acids, *et cetera*, easily oxidise it without the aid of heat; sulphuric acid, when diluted, has no action upon the metal, even when aided by heat, but concentrated acid, at a high temperature, readily converts it into a proto-sulphate, sulphurous acid being eliminated. With selenium, sulphur, phosphorus, chlorine, bromine, and iodine, it unites with facility, giving rise to the haloid mercurial compounds of those radicals. It quickly combines with the noble metals—also with tin, lead, bismuth, zinc, and most of the soft metals, giving rise to amalgams which often possess particular interest. This is the case, more especially in a manufacturing sense, with the amalgams it constitutes with gold, silver, platinum, as they are available in the smelting or abstraction of these metals from the gangue in which they may be distributed. Indeed, a chief portion of the mercury annually extracted is devoted to this special application, so that a distinct relation between the yearly production of gold and mercury may be traced. Besides this application it has many others, such as gilding, plating, and the like. Many of its compounds are valuable in other branches of art, such as medicine, painting, *et cetera*, but more particularly in the former, where its administration is very varied and frequent. The metal is likewise very advantageous to the anatomist, who employs it as an injection, either alone or in the form of vermilion suspended in size. There are many other instances of its application, but not being very general, they will not be further dwelt upon.

Atomic Weight.—Before proceeding to notice the ores of mercury and the processes by which the metal is obtained from them, it may be mentioned that much difference of opinion has existed respecting the atomic weight of this element. The mercurial oxides are two in number—the *grey* and the *red*; and it is from the different view chemists have taken of the constitution of these bodies that 100 and 200, or a near approximation, have been respectively proposed as the equivalent of mercury. The composition of these bodies, denominated mercurous and mercuric oxides, is thus centesimally expressed:—

	Grey Oxide.	Red Oxide.
Mercury,	96.15	92.59
Oxygen,	3.85	7.41
	100.00	100.00

Now, if the *grey* be assumed to be the *protoxide*, then the value of an equivalent of mercury capable of saturating a full equivalent of oxygen, which is represented by 8, will be 199.8, or nearly 200; whilst, on the other hand, assuming this oxide to be the suboxide, and, halving that number, it will be represented by two equivalents of metal, and one of oxygen. Taking the equivalent of the metal, then, at 100, the atomic constitution of these oxides is thus represented:—

Grey oxide.		Red oxide.	
2 Eqs. Mercury,	200	1 Eq. Mercury,	100
1 Eq. Oxygen,	8	1 Eq. Oxygen,	8
1 Eq. Grey Suboxide, 208		1 Eq. Red Protoxide, 108	

The chemical symbol of the metal is taken from its Latin name, and is written Hg.

BERZELIUS, ERDMANN, MARCHAND, GMELIN, REGNAULT, THOMSON, GRAHAM, and many other chemists, have adopted 100 or something near it as the true atomic weight, and the preference is further justified by the fact, that though both oxides are salifiable, yet the grey is very unstable, and unlike a true protoxide in its characters, whilst the red is eminently persistent and basic; indeed, according to BRANDE, it almost approaches to alkalinity. Besides, the evidence adduced from the connection of the atomic heat of the metal with its atomic weight is decidedly favorable to that number which expresses the grey as a *sub*, and the red as a *protoxide*. The experiments of STRANBERG, published in the Memoirs of the Academy of Stockholm for 1845, go to prove that the atomic weight of mercury cannot be less than 99.90.

ORES OF MERCURY.—The minerals into the composition of which mercury enters, are by no means numerous, and few of them are important. The metal itself occurs native in the form of fluid globules scattered through its gangue. The quicksilver mines of Almaden in Spain, of Idria in Carniola, of Wölfsstein and Morsfeld in the Palatinate of Rosena in Hungary, and Sala in Sweden, supply specimens of the virgin metal, which was said at one time to fetch a higher price than that obtained by reduction. In some places native mercury is so plentifully dispersed through its ores, that when an opening is made it escapes, and trickling out, collects in considerable quantities at the bottoms of the levels.

A native amalgam of silver, amorphous and crystallised, is also met with. Not unfrequently this mineral occurs in the form of flattened plates. A specimen, said to be from Peru, the specific gravity of which Dr. DALZELL determined, did not exceed 13.995, but usually it is 14.119. From the average of the analyses of three specimens examined some years ago by the same chemist, along with the analysis of other specimens by KLAPROTH and CORDIER, it consists centesimally of—

	Dalzell.	Klaproth.	Cordier.
Mercury,.....	56.1	64.	72.5
Silver,.....	43.9	36.	27.5
	100.0	100.	100.0

That the composition of this mineral should vary considerably does not seem surprising, since it has been proved that mercury evaporates from mercurial ointment and amalgams. *Argirite*, an argentiferous amalgam of great value, is found in considerable quantity in the province of Coquimbo in Chili. It contains 13.5 parts of mercury, and as much as 86.5 per cent. of silver. Indeed, this is one of the chief ores of silver in the rich mines of Arguiros. An amalgam of gold, analysed by SCHNEIDER, and which occurred along with platinum ore from Columbia, contained mercury 57.40, gold 38.39, and silver 5.0. Native amalgams of lead, containing selenium, have been analysed by ROSÉ.

Horn quicksilver—subchloride of mercury, or native calomel—is found associated with the other ores of quicksilver at Idria, at Deux-Ponts, in Spain, and elsewhere. It is a yellowish or ash-grey mineral, sectile, and subtranslucent. Sometimes it occurs as a crust, or forms granular concretions. At other times it crystallizes in four-sided prisms. Its specific gravity is 6.482, whilst that of the powdered calomel of the shops is 7.14, and that of the crystallized factitious subchloride is 7.2.

Iodides, bromides, and selenides of mercury also occur, but rarely. The iodide has been met with in Mexico, associated with the selenide. A specimen of the bromide Dr. DALZELL found to contain, besides bromine, traces of iodine, selenium, and sulphur. ROSÉ has described the selenide as composed of selenium 6.49, sulphur 10.30, and mercury 81.33.

The principal ore of mercury is the sulphide—the *zinnober* of the Germans and *minium* of PLINY. The color of native cinnabar varies from cochineal red to brownish-red and leaden grey. The streak is scarlet, and the lustre usually adamantine. The density of this mineral is 8.098, and when pure it contains 86.29 parts of mercury with 13.71 of sulphur. Specimens of the purest ore have, occasionally, all the richness of hue which the best vermilion presents.

The following table shows the composition of cinnabar from various quarters of the world, the amount of the constituents being centesimally expressed :—

Geologically, the ores of mercury occur amongst stratified deposits. The volatility of the metal may account for its not being met with in any large quantity in

crystalline or igneous rocks. Thus, it is found most abundantly in the independent coal formation, and in beds lying between primitive argillaceous schistus and

chlorite slate, associated with quartz, calcareous spar, spathic iron, and copper pyrites. In the famous quicksilver mines of Almaden in the province of La Mancha, a few miles from the frontier of Estremadura, which have been worked for many centuries, the veins traverse micaceous transition schists and sandstone grit, intersected here and there by granitic and porphyritic eruptions. A portion of the Almaden ore is extremely rich; but the larger proportion is so intermixed with quartzose and argillaceous gangues, that the yield is not over ten per cent. of metal. At Quença in New Granada, Durasno in Mexico, and in some of the Peruvian mines, the mercurial ore occurs in the red sandstone above the coal; whilst at Deux-Ponts, at San Juan de la Chica in Peru, and in some other localities, it is placed in the subordinate porphyry. The mines of Idria are worked in a friable compound of dark carbonate of lime, and argillaceous schist. These mines were discovered in 1497, before which time the country was inhabited only by a few artificers in wood. Tradition thus records their discovery:—A cooper having one evening placed a new butt under a neighboring spring to try if it would hold water, when he returned the next morning to take it away, found it so heavy that he could with difficulty move it. Being an ignorant man he at first supposed his vessel was bewitched; but at length perceiving that it contained a heavy and brilliant liquid metal, he carried away some of it, and showed it to an apothecary in Laubach, who, being better informed than the peasant, and more cunning, kept the mercury, sent the man away with a small gratuity, and directed him to bring him all he could obtain. This the cooper did for a considerable time, till the affair became known, when a society was formed, and a further search for quicksilver instituted. The mines remained in possession of this society till the Archduke Charles of Austria, perceiving their importance, purchased the properties, and took the mines of Idria also under his control.

The subterranean passages of these mines are extensive; but owing to the loose and friable nature of the ground, large excavations are impossible. Their greatest perpendicular depth, taken from the entrance of the shaft, is about eight hundred feet; but as the galleries advance horizontally under a high mountain, the depth would be much greater if measured from the surface of the hill. The mine was formerly entered either by descending the shaft in a bucket, or by zig-zag ladders. By the first route the visitor was subjected to the inconvenience and danger of being stopped by some projection; or the bucket might even strike against the side and be upset. Nor was the ladder descent more safe and agreeable; for the steps being wet, slippery, and narrow, the utmost caution was requisite to prevent falling. Now, however, the entrance is through a large iron gate, by a horizontal passage to a descending flight of seven hundred and fifty-seven steps, cut in the limestone rock, and provided with a hand-rail. At the bottom of these steps there is a small chapel in which the miners perform their devotions, and from which a labyrinth of passages opens out. In some of the galleries the heat is so intense as to be almost insupportable. The noxious inhalations of the metal speedily

become so offensive that the visitor is glad to make his escape. The ascent is usually performed by a perpendicular shaft at a considerable distance from the spot where he entered, and through which he is raised in a cage or bucket.

In 1803 a fire broke out in the workings, and was with great difficulty extinguished. Fumes of mercury filled the air; and throughout the neighborhood, nine hundred people were affected with the most urgent symptoms of mercurial poisoning.

These mines continue to be worked by the Austrian government, which restricts their annual yield to one hundred and fifty tons. URE states, that but for this avaricious enactment for keeping up the price of mercury, six hundred tons would easily be produced yearly. Some of the ore yields fifty to sixty per cent. of metal. The richest qualities are termed *stahlerz*; and the poorer, bituminous sulphide, averaging only ten per cent., are called *zeigelerz*.

Besides the quicksilver works, there is a manufactory of cinnabar, which annually produces about ninety tons. Benevolent institutions have also been established for the treatment of those miners whose health has suffered from the action of the mercurial fumes.

The mercury mines of the Palatinate are not equal in richness and importance to those of Idria and Almaden. The workings at Drey-Koenigszug, at Potzberg near Kussel, give an annual yield of about thirty tons.—PHILLIPS. The ore there is sandstone, intimately mixed with sulphide; and the depth to which the explorations have been carried exceeds six hundred and sixty feet. The aggregate yearly average of several still smaller mines in Hungary, Bohemia, and other parts of Germany, does not, according to URE, exceed thirty to forty tons. The quicksilver mines of Huancavalica in Peru, the products of which are employed in the treatment of the gold and silver ores which abound in that neighborhood, have been worked since 1570. Up to 1800 their produce was fifty-three thousand seven hundred tons of quicksilver.

Several accounts of the Californian quicksilver mines of New Almaden have been published. The following early notice was communicated to Silliman's *Journal* by the REV. C. S. LYMAN, in a letter dated—Pueblo de San José, March 24, 1848—not quite two years before the supply from this quarter reduced the price of mercury:—The mine of New Almaden is situated a few miles from the coast, about midway from San Francisco and Monterey, and in one of the ridges of Sierra Azul mountain. The mouth of the mine is a few yards down from the summit of the highest hill that has yet been found to contain quicksilver, and is about twelve hundred feet above the neighboring plain, and not much more above the ocean. This hill extends longitudinally in a north-west direction, decreasing in height; and in various parts of it, for several miles, traces of the ore have been found, and some openings have been made which promise to be valuable. This range of hills consists of a variety of rocks—the prevailing one is a greenish talcose rock, which seems to embrace the bed of ore at the New Almaden mine, both above and below. The ore is interspersed through a yellow ochreous matrix, which forms a bed forty-two

feet in thickness, dipping north-westerly at an angle of about 45°. The richest ore is at present found in the upper part of the bed; the poorest ores being taken from the lowest portion.

This mine, known to the aborigines from time immemorial as a *cave of red earth* from which they obtained paint for their bodies, was first discovered to contain quicksilver about four years since, during experiments made by some Mexicans to smelt the ore for the purpose of obtaining *gold*, which they supposed it to contain. About two years ago it fell into the hands of BARROW, FORBES, and Company, who commenced working it. The great trouble was to obtain suitable apparatus for extracting the metal. At length four potassa kettles were found, which were set in a furnace of adobes, with condensers of mason work immediately adjacent,—a wretched apparatus indeed for managing a thing so subtle as mercurial vapor. The daily mode of working was to fill these pots in the morning with one thousand six hundred pounds—four hundred to each pot—of the ores of average quality, broken in lumps of the size of apples, put on the covers, and lute them with a layer of *sand*. The fires were then kept up till near night, when the furnaces were allowed to cool gradually. The next morning the condensers were opened, and the metal dipped up, which usually amounted to from two to three hundred pounds from the four pots. This was a much less per centage than the usual assay indicated, and it was obvious a large portion of the metal was lost. The upper part of the pots and condensers was found to be generally covered with a crust of sulphide of mercury. Mr. FORBES wished to devise some way of extracting the metal without mixing lime with the ore in roasting, but was unsuccessful. At length a kiln of lime, which occurs in the immediate vicinity was burned, and I am informed that the ores yield with this a vastly greater per centage of metal. In the last three weeks, about ten thousand pounds of metal have been extracted with the same apparatus, being a yield of over fifty per cent. The mine is probably giving a net profit of one hundred thousand dollars a year, with its present crude apparatus. With suitable furnaces, and iron cylinders or retorts, the mine would easily yield a million and upwards.—*Lyman*.

New Almaden, writes Mr. RUSSEL BARTLETT in 1853—that is five years later—now consists exclusively of the buildings belonging to the Company which owns the quicksilver mine. It embraces furnaces, store-houses, dwelling-houses for the officers and laborers, offices, mechanics' shops, *et cetera*. Many of them are of wood, but a large and fine range of substantial brick buildings is now in process of erection to take the place of the wooden ones; six furnaces are now in operation reducing the ore, all of which seem to be alike and of the most simple construction; the furnaces are kept going night and day, and the metal is collected in tanks, the largest of which holds twenty tons. The Californian metal comes into the market in wrought iron bottles, screw stoppered, and holding seventy-five pounds each. The bottle itself weighs about twenty-five pounds. A land carriage of about twenty miles, performed in the ore carts, brings them to the point for shipment. The New Almaden produce in

1853, equalled one hundred thousand bottles per month, or one million per annum. During the same year the following exports from San Francisco took place, the whole of the metal being the produce of the New Almaden mine.

Further particulars of this interesting mine were published in 1856, in the *American Journal of Pharmacy*. The present entrance to the workings is by a horizontal shaft and railway twelve hundred feet long. The large masses of rich and compact ore, some of which weigh as much as twenty pounds, are separated from the small fragments which are mixed up with yellowish earth and clay. The latter are pounded, kneaded up with water, and dried in the sun; thus baked, they are called *adobés*. The smelting furnaces, of which with their condensing chambers there are fourteen, are situated a mile and a quarter from the entrance to the mine. Each range consists of a fire chamber three feet by five, placed at the end of a series of eight or ten chambers, seven feet long, four wide, and five high. The range is built of brick, plastered inside, and protected against expansion by heat by iron rods passing from wall to wall, and secured with screws and nuts. The tops are of boiler plate, luted with salt and ashes. The first or fire chamber is separated from the second or ore chamber by a network partition of fire-brick. The third chamber communicates with the ore chamber by a square opening at the right upper corner, and this first condensing chamber with the second, by a similar opening at the left lower corner, and so on; the top openings being on the right, and the lower openings on the left, alternately. From the last condensing chamber the vapors pass into a wooden hose, in which there is a continuous shower of cold water, while any uncondensed matters pass into the open air through tall wooden flues. The floors of the condensers are guttered, and by these the mercury flows into an open conduit, from the end of which it pours over a brush into the iron bottles already described.

The lumps of cinnabar and the *adobés* are piled like bricks in the second chamber, a wood fire is lighted in the furnace, and the flame plays through the brick network on the ore. Each ore chamber, when fully charged, contains ten thousand pounds of cinnabar, to exhaust which requires sixty hours. At this period, lime appears not to be used in the reduction of the ore. RUSCHENBERGER conceives that the addition of this substance would increase the yield, but not, he adds, sufficiently to pay the cost of the earth. This is singular, as LYMAN speaks of lime occurring in the immediate vicinity.

Assay of Mercurial Ores.—It may be well to state

here the means by which ores of mercury may be assayed, more with the view of showing how much metal should be obtained on the large scale, rather than giving a precise method of analysis. The methods followed are distillation of the product, whether it be oxide, chloride, sulphide, selenide, or iodide, with caustic lime; if only a sulphide be present, simply subliming it; but this offers no advantages, since a higher heat is required, and there is always a liability of a portion being reduced, the metal passing over with the cinabar, and exposing the results to error.

When lime is employed, from fifteen to twenty-five parts may be taken, according to the richness of the assay. This is intimately blended in a mortar with the finely ground ore, together with a tenth of the weight of the ore operated upon, of fine charcoal, and the whole introduced into an earthen or hard glass retort, with a long neck, and surrounded with cloths, on which a stream of water may be kept flowing for the purpose of condensing the vapors. The beak of the retort should likewise be inserted in a flask kept cool by wet cloths. The distillation may be carried on over a gas flame; or better, by means of a small charcoal fire and sandbath. All the mercury is transported into the neck of the retort in the state of vapor, where it condenses, and trickles into the receiver. When no more vapors arise, and the materials are carried to dull redness, the fire is removed, and any globules which may remain in the neck of the retort, made to flow over into the receiver by tapping it gently, or introducing a small brush; and after the whole has been collected, the product is weighed. In this way the yield of mercury is ascertained with a degree of accuracy which will be dependent upon the carefulness of the operator. The sulphur, or other mineralizing element of the ore, will remain united to the lime, or else form gaseous products with the carbon, and be retained or evolved according to their nature. Iron scales or carbonate of soda may be employed with equal effect; only, in case of iron being the agent, it should be finely divided and used in excess, to insure that none of the mercurial body may escape decomposition. When the experiments are carefully managed, the result in either case is very exact. Instead of using charcoal, hydrogen gas may be passed over the assay during the sublimation; but this is inconvenient, excepting where the resources of a well-regulated laboratory are available; and, besides, it does not make the results more correct in the hands of a careful assayer.

Reduction of Mercurial Ores on the large scale.—There is, with a few exceptions, very little diversity in the manner in which the smelting of mercurial ores is carried on. It is strange, however, that in the case of the largest and most important *lode* in the world, that of Almaden, the comparatively rude and inefficient method of working invented by JUAN ALONSA BUSTAMANTE more than two hundred years ago, should still be followed in all its details; a method which, however remarkable and advantageous it might appear at that period, is now acknowledged to be much more laborious and incomplete than several others which are in practice at other mines of this kind. The defect of the system does not only directly affect the quantity of

mercury extracted, and which, according to the testimony of M. LE PLAY, is far below the per centage contained in the ore, but, likewise, the workpeople in, and inhabitants of, the districts adjoining the seat of operations, in consequence of the baneful effects of the escaping mercurial vapors on the system. LE PLAY speaks upon this subject thus:—*Le mercure a sur la santé des ouvriers la plus funeste influence, et l'on ne peut se défendre d'un sentiment pénible en voyant l'impresement avec lequel des jeunes gens, pleins de force et de santé, se disputent la faveur d'aller chercher, dans les mines, des maladies cruelles, et souvent une mort prématurée.* JUSSIET, on the contrary, states, that the vapors which escape from the chambers of condensation at those works, have no pernicious effect either upon the inhabitants or vegetation in their neighborhood; still, from the consideration of the process, and the imperfections evident in it, coupled with the known noxiousness of mercurial fumes, every attentive observer would be led to conclude that life and vegetation must suffer to a great extent both in and around the factory.

Figs. 356 and 357 represent a section and plan of the kind of apparatus employed, which is known as the *butyrone* or *aludel* furnace. It consists of a circular or polygonal chamber, A A, about four feet in diameter, and divided into two compartments by a perforated

Fig. 356.

Fig. 357.

brick arch, B, about nine feet from the top. The heat is obtained from brushwood introduced at the aperture, c, into the fireplace, a, and the smoke is carried off in part by the chimney, d. A door, e, in the side of the cylinder, and an aperture, f, at the top, are used to introduce the charge of ore, the volatile products of

Fig. 358.

which escape into the condensing media by a system of openings, g, and which communicate with files of condensers of earthenware, called *aludels*, h, connected one with another, as represented in Fig. 358. These are laid on two planes of brickwork, inclining to

one another, supported on arches, as represented in Fig. 356. Where the two planes meet is a channel or gutter, *i*, leading to a conduit, *l*, in the brickwork, and thence by wooden pipes at the bottom to the receiving basins, *j j*, partly filled with water, and fixed in the floor of the smelting room. During the passage of the distilled vapors through the several files of aludels, the metal which condenses flows for the most part into the aludel which crosses the channel, *i*, and issues into the latter by a hole in its under part; the uncondensed products pass into the upper part of a condensing chamber, *k*, and are conducted towards the bottom by a screen, where a cistern of cold water receives the metal. Such portions as diffuse themselves in the chambers are deposited on the walls, in form of soot, and are from time to time brushed off and collected at the bottom. Sulphurous and other gases pass off by the chimney, *l*, but sometimes a second chamber is above the arch of the first, in which a further quantity of the metal is retained. Whatever is collected in this way is filtered, in order to purify it from other matters, and the dross is worked up with loam and fine or powder ore into bricks, and subsequently distilled over again. The charge of ore for this furnace averages from two hundred and twenty to two hundred and seventy hundredweight, and is divided into three varieties, each of which occupies particular places in the furnace. The larger pieces of the sandstone rock, slightly impregnated with cinnabar, and called *soleras*, are placed on the arch immediately above the fire. Being too poor to be worked by themselves, and requiring too much labour for preliminary dressing, it is worked off in this part of the furnace. Above the *soleras*, about twenty-two hundreds of rich mineral are laid on, then some poor ore in small fragments, and the remaining space is filled with the dross from the aludels and condensing chambers, some fine ore previously worked up with some clay and moulded into bricks. The door in the side, and also the aperture in the top, are then secured by the doors, and covers, and luting. After this, the adapters are arranged in proper order on the inclined planes, and the joinings secured by clay luting. The number of these vessels being so large, a good deal of time and labor is required for this work. There are six files in each bench, and forty-four vessels in each file, making, for the entire furnace, about five hundred and twenty-eight. From the aperture of the furnace to the condensing-chamber, the length is about sixty-five feet, so that each aludel is more than eighteen inches long. All things being ready, the fire is lighted and kept in active ignition by the supply of fresh brushwood. An abundant flame is thus produced, which passes up through the apertures in the arch of the furnace, and heats, first the *soleras*, and subsequently the remaining contents, and drives the whole of the metal into the aludels, volatilizing it with the sulphur in the form of sulphurous acid with a little sulphuric acid. According as the aludels become heated by the vapors, they begin to act more effectually the part of a series of chimneys, and so draw off the products more freely. The fire continues successively for twelve days to work off the charge, after which time it is permitted to die out; and three days further are

allowed to cool the earthen adapters before they are detached, and the portion of mercury in them collected. This work also consumes a good deal of labor, as each receiver, after being detached, is to be brought to the channel midway to be emptied. Any metal shed in the carriage, runs along the incline, but is not lost; it becomes soiled, however, so that it is necessary to submit the whole to a purifying process. That adopted is very simple, merely pouring the metal on the floor of the room destined for the work, which being slightly inclined towards one end, the metal flows down clean and bright into a receiver, and leaves the dross and soot behind it adhering to the floor. A good deal of metal remains in the residue; hence it is carefully collected and worked up in the next charge. Each charge affords from twenty-five hundred to three thousand pounds of mercury; sometimes, when the ore is a richer kind, as much as six thousand pounds are obtained; but the manager tries to average the ore, so that the yield may be about the first-mentioned quantity. If the charge be enriched by using more of the purer ore, the loss in mercury is considerably greater than if only an average kind be worked; besides, the trouble arising from the cracking of the lutes securing the connection of the aludels, and their renovation, is multiplied. This was particularly remarked in 1787, when an innovation was made in the ordinary course of working, by employing a larger quantity of rich ore than that already mentioned. Fully half the metal in the surplus was lost, owing to the draught of the aludels being inadequate to carry it off, and the injury to the health of the smelters from breathing so much mercurial vapors was very serious. Besides the mercury, another substance is found to encrust the earthen cones, which PROUST found to contain—

	100.0

The same chemist estimates the extent of its formation at about forty pounds per charge, or in its content of metal equal to 1.500 of the weight of the rich mineral wrought, and attributes the presence of the subchloride to its being contained in the ore, and volatilized as such. Doubtless portions of this compound do exist in it, but it is likely also that a chloride is produced by a process of double decomposition that takes place between portions of the cinnabar and the alkaline chlorides in the particles of ash which are drawn up into the furnace by the draught; or a sulphate of mercury may be formed during the roasting of the ore or in the aludels, and this, in contact with the chlorides already mentioned, may produce the effect; or the chlorides meeting the continually-forming sulphuric acid may be decomposed, setting free hydrochloric acid, which, passing over the sulphate of mercury condensed in the aludels, gives rise to the calomel and free

sulphuric acid. This loss is now, in part, avoided by mixing some quicklime with the *schlich* and clay in making the bricks, which occupy the upper space near the dome of the furnace. Cast-iron cylinders, bent, and surrounded with water, have been tried at Almaden, as a substitute for the aludels, but their use has been abandoned, in consequence of their being rapidly corroded by the free acid, although the mercury was found to condense very well in them. PROUST likewise analyzed the incrustation on these condensing pipes, and found—

The alum arose from the action of the sulphuric acid on the clay pipes which connected the iron condensers with the outlets of the furnace, and the potassa was supplied from the ashes of the fuel.

A portion of the Almaden mines, probably that now called Little Almaden, was worked by the Romans. PLINY speaks of *Sisapo*, a territory of *Batica*, the mine of *minium* there forming a part of the revenues of the Roman people. Indeed, adds the same historian, there is nothing guarded with a more constant circumspection; for it is not allowable to reduce and refine the ore upon the spot, it being brought to Rome in a crude state, and under seal, to the amount of about two thousand pounds per annum. The modern town, which contains about seven thousand inhabitants, is built over the principal mine, the entrance to which is close to the houses, and the ascent and descent of the miners effected by ladders. Not long ago, and possibly even now, the water was pumped from the mine by a WATT engine, made about the year 1790! The produce of the workings is drawn to the surface by mules, up a wide and well-constructed stone shaft. Convict labour was formerly employed by the Spanish government, but now free workmen, to the number of about five thousand, have been substituted, who work almost naked, and from Spain receive a high rate of wages. Their health, however, always suffers; but, as the workings are only carried on during winter, a release from confinement, with fresh air during the summer, usually restores them to health, and permits of their return to labor on the opening of the mines.

The produce of the Almaden mines, which is sent to Cadiz and Seville for exportation, is packed in cylindrical cast-iron bottles, which are closed with a screw stopper. Each bottle contains three Spanish *arobas*, making seventy English pounds net per bottle. But the weight charged by the importers is on an average only sixty-nine to seventy pounds, arising from the tret of four pounds per every one hundred and four pounds; and one pound draft being allowed, and the tare being fixed at eight pounds, whilst the real tare averages sixteen to seventeen pounds.—*Pereira*. In the sixteenth century

these mines were rented by the brothers MARK and CHRISTOPHER FUGGER, the rich capitalists of Augsburg, under a contract for the payment of four thousand five hundred quintals of mercury yearly to the government. Unable to fulfil their agreement, they relinquished them in 1635. Ten years later, the Spanish government undertook their management. In 1831 N. M. ROTHSCHILD and SONS obtained from the Spanish government the contract for all the mercury they produced. With this monopoly the price, which in 1831 was one shilling and ten pence per pound, rose in 1849 to four shillings, whilst the cost of mercurial salts rose in the same proportion. Before 1850, however, Californian mercury appeared in the market, when the price of the metal per pound fell in the course of four years to two shillings and a penny.

Method of Reduction at Idria.—This famous mine was discovered so far back as 1497, but the working of the ore was very irregularly prosecuted for nearly a century afterwards, and even then there was no fixed establishment, but the ore and utensils necessary were carried about in the forests to where the charcoal-burner had chosen the site for his *meiler*, in order to make the heat of the burning wood available for the reduction of the ore. A number of earthen pots, with narrow necks, were filled with the ore, mixed sometimes with lime; the mouth was then stopped with a clay plug, so as to retain the charge, but allow the fluid metal to flow out into a wide-mouthed vessel, into which the charged one was inverted. As many of these as would fit in the base of the charcoal heap were arranged as described, and the clay or soil raised about the subjacent condensing pots, the connection between the two luted, and the wood arranged in the usual way for charring. During the combustion of the wood the heat was sufficient to set free the metal which collected in the bottom pot. This method of distillation *per descensum* was extremely wasteful. In 1635 there was a fixed establishment erected, and the gallery furnace analogous to that at the Palatinate, which shall be described further on, adopted; in 1750 the Almaden system was introduced—and, finally, at the close of the last century, the aludel furnace was substituted by the present arrangement. The commencement of the present Idrian process is the assortment of the ores into two classes, according to the size of the pieces. All from the size of a cubic foot to that of a nut belong to No. 1; smaller pieces, and the dust, to No. 2. In No. 1 are further subclassified—*a*, the poorest portions, yielding only about one per cent.; *b*, the pure sulphide, yielding nearly eighty per cent.; and *c*, fragments of various richness averaging from one to forty per cent. The subclasses of No. 2 consist of—*d*, fragments from the mine, yielding from ten to twelve per cent.; *e*, particles separated on the sieve, yielding about thirty-two per cent; and lastly, *f*, the *schlich* obtained from the washings, containing eight parts of the metal in a hundred.

Figs. 359 and 360 are a plan and elevated section of the great distillatory furnace erected at Idria. In the latter figure only one of the furnaces are seen, although there are two in the same block with a double row of condensing chambers, as represented in the plan. *a a'*

are the fire doors; *b*, the hearth where the fuel is consumed, and above which is the body, *d*, of the furnace, divided by perforated arches into three compartments, the top one being in communication with the first condensing chamber on either side, by flues, *ee'*. There are

Fig. 359.

Fig. 360.

six chambers at each side of the furnace, *f, g, h, i, j, k, l*, the connection of one with another being placed alternately near the top and bottom, as at *f', g', h', i', j', and k'*, with the view of bringing the vapors over as much space as possible, that in the course of which they might deposit the quicksilver. Each of these chambers has an outlet, *s*, by which the condensed metal flows out into a receiver, *m m*, whence it is conducted by a conduit, *nn*, into the main tank. They have likewise an aperture at the top, which is closed, as also that at the base, during the period that the furnace is working. The last chamber in the series is usually furnished with a number of flanges, or inclined boards, which reach in a slanting direction almost to the opposite wall, upon which a stream of water is continually

Fig. 361.

falling from the top, so that the vapors, as they ascend through it, follow a sinuous course, and deposit the last traces of metal as they meet the flanges. *pp', qq'*, are arches which conduct air to the fire and interior of the furnace, for the oxidation or burning of the sulphur. By side-doors opening into the several compartments of the furnace, the ore is introduced; these are closed whilst the charge is being fired. The largest and poorest pieces of ore are placed on the first arch, and

the smaller ones in overlying beds till this part is full; in the next, the smaller fragments, which, however, allow sufficient space for the passage of the vapors, are deposited, and the upper compartment receives a number of earthen trays filled with the fine powder or *schlich*. All the spaces being thus replenished, and the doors and other apertures, where an escape would be possible, secured and luted, a brisk fire of beech or fir wood is made on the hearth, *b*, and maintained till the furnace acquires gradually a cherry-red heat; it is then kept at this degree for ten to twelve hours, during which the distillation lasts. The high temperature of the developed vapors, coupled with the great height of the furnace—about thirty feet—and the number of chambers that are in connection with it, create at the first a quick draught, which is sustained while the distillation continues. This is absolutely necessary, in order to draw as much air into the furnace as will suffice for the oxidation of the sulphur into sulphurous acid, and its removal from the metal. All the products of combustion, as well from the ore as from the fire, pass into the chambers, where they condense in part, the mercury falling upon the inclined slabs at the bottom, and collecting there, and the portions of cinnabar and mercurial soot forming upon the walls. The furnace is allowed five or six days to cool and condense the metal, at the end of which the upper apertures are opened, the portion condensed on the bottom drawn off, the walls brushed down, the separated mercury collected with the rest, and the grey powder and cinnabar gathered and put to one side, to be worked up in the next charge. This done, preparation is made to recharge and repeat the same process just described. One charge a week is the most that can be worked under these circumstances, and this charge, for the double furnace, amounts to ten or twelve hundred quintals, of one hundred and eight pounds avoirdupois each. A gang of forty men are employed in the charging, and the work lasts them three hours.

The yield of each charge averages eighty to ninety quintals of metal.

Lastly, the mercury is filtered through ticking cloth, and is then packed in cast-iron bottles for exportation. Each bottle contains sixty pounds. Only one such operation as has been described, can be effected weekly, since five or six days are required to cool the furnace, which is one hundred and eighty feet long, and thirty feet high.

Much inconvenience and injury attend the workmen at this establishment, owing to the dangerous effects of the mercury, inhaled whilst brushing down the walls of the chambers,—an operation which exposes the men to the vapors for two hours. Hence, it is no strange occurrence to observe many of the operatives salivated or affected with nervous tremblings.

DUMAS suggests, that to make the establishment at Idria continuous in its operations, it would be necessary only to multiply the chambers of condensation, and substitute for the furnace at present erected, another on the principle of a continuous lime-kiln, the ore being charged in large pieces, and the *schlich* worked up into bricks or balls with clay, and introduced into the upper part. With such modifications this method

would be, according to the last mentioned *savant*, the best in use; but the writer can hardly help thinking with URE, that it is most unchemical in its present aspect, and out of keeping with what might be supposed to exist in these, the second most extensive quicksilver works in the world.

A different system to that followed at Almaden and Idria, as well in principle as in manipulation, is pursued in the mercury smelting works of the duchy of Deux Ponts. In the former, the principle of the changes is the removal of the sulphur by its combustion into sulphurous and sulphuric acids, and with this view the furnaces are constructed, so that the air is freely drawn through them at the temperature necessary to cause the expulsion of the sulphur. In the latter, the same ends are attained—not, however, by roasting, but by the addition of bodies which take the sulphur from the valuable metal, by a process of chemical decomposition. Lime is the body always resorted to, it being the most plentiful and cheapest; but scales or grains of iron would likewise answer, and the heat causes the formation of a sulphide of calcium or of iron, and sets free the mercury which is driven off in vapor, thus:—

that is, four equivalents of sulphide of mercury, and four equivalents of lime, afford the whole of the metal, three equivalents of sulphide of calcium, and one of sulphate of lime. This decomposition is more complex than that effected by roasting, as may be seen from the following formula:— $\text{Hg S} + \text{O}_2 = \text{Hg} + \text{SO}_2$. But the volume of hot gaseous matter from which the mercury is to be condensed, necessitates the use of an extensive range of cooling media, whereas, in the distillation with lime, these are not required, as only the metallic vapors are emitted.

In the duchy of Deux-Ponts, mercurial ores, mixed with lime, are heated in earthenware retorts furnished

Fig. 362.

with receivers of the same material. A vertical section of the furnace gallery of the Palatinate is shown at Fig. 362. AA represent earthen cucurbits with their receivers, BB. Each of the former is filled about two-thirds with a charge containing ore and quicklime in the

proportion of sixty to sixteen, and the receivers are at the same time half filled with water. The retorts are arranged in a double row, one above the other. In this way from thirty to fifty-two cucurbits are included in one *gallery*. The fire, which is from pit-coal, is placed on a grate beneath them, and a draft is secured by means of apertures in the arched roof. When the mercurial gangue is sufficiently calcareous, it is only necessary to moisten and distil it. As soon as the mass in the retorts is exhausted, the contents of the receivers are emptied into a wooden basin standing over a bucket; the object of this operation being to draw off, along with the water which falls over the sides of the bowl, all the black sulphide with which the metal is mixed up. This black matter is afterwards taken up, dried, and again distilled with excess of lime.

Method pursued at Lansberg.—One other metallurgic apparatus for the reduction of mercurial ores,

Fig. 363.

remains to be described. It is in use at Lansberg, near Obermoschel, in the Bavarian Rhein-Kreis, where it was erected in 1847, and is the contrivance of the late Dr. URE, who has thus figured and described it:—Fig. 363 is a section parallel to the front elevation of three arched benches of retorts. Each bench con-

Fig. 364.

tains three of these vessels, *aaa*, constructed of cast-iron, and somewhat like those employed in the manufacture of coal gas; the whole are set in masonry, the bottom of the uppermost retort being protected from the direct impingement of the flame by fire tiles. The

dotted lines leading to $\kappa \kappa$, show the direction of the chimneys. In Fig. 364, is represented in section the body of one of these retorts. The mouth on the right of the figure is closed with an iron lid, which is bolted, barred, and luted, after the charge has been introduced. An iron pipe, four inches in diameter, and having a nozzle hole at L , dips into the main condenser, C , and the same arrangement is shown at another section at Fig. 365, where $C C$ gives a longitudinal view of the main condenser, which consists of a pipe twenty feet

Fig. 365.

long, and eighteen inches in diameter. The backs of the retorts are shown at aa , and the eduction-tubes in the same figure at bb , dipping a short way beneath the surface of the water. At z is placed a water valve to obviate the risk of sudden expansion or condensation from inequalities of temperature, and at i is depicted a water trough, or outer vessel of wood, in which the condenser is placed. The inclination of the condenser is towards the left, so as to favor the exit of the mercury by the vertical delivery tube, d , into the lock-up reservoir, e . The end of this tube dips from the first into a small cistern of mercury, and at k is shown a floating and graduated gauge rod by which the quantity of mercury in the chest, e , may be always ascertained without the trouble of opening it.

Before charging the retorts, the ore is reduced to a coarse powder, then mixed with quicklime, and shovelled in. Six or seven hundredweight of the mixture, a sufficient charge for each retort, can, with a proper amount of heat, be worked off in about three hours. The process is continuous, and, with an efficient staff of workmen, could be daily made, by using nine such retorts, to decompose six tons of the mixture—a quantity which, if the ore was rich like that of the Idria or Almaden mines, would equal twelve hundred to a ton of mercury daily.

It is singular that the imperfect process of condensation by such barbarous apparatus as *aludels*, or the rude and cumbrous furnaces of Idria, should not have been superseded by an arrangement similar to, or equally efficient with, that just described. The outlay would be repaid in the course of a few months by the expedition with which continuous yields of metal could be obtained, and an enormous saving would take place through the complete condensation of the metallic vapors; whilst the duties of humanity would be attended to, and many, if not indeed all, of the miserable results of a poisoned atmosphere, would be avoided.

Purification of Mercury.—If, as is sometimes the case, the mercurial ore contains bismuth or zinc, portions of these metals will be carried over with the distillate. Lead, antimony, and tin, may also be present as adul-

terations, having been fraudulently introduced. Various methods have been devised for rendering the metal chemically pure. WITTSTEIN recommends, where not more than three pounds are operated on at once, that its redistillation should be effected in a small plain retort of thick glass, clean iron turnings being added to the mercury, in the proportion of one of the former to twelve of the latter. The retort rests in a deep sand bath, which is placed in a furnace; as much inclination as possible being given to the neck of the vessel, which should be lengthened with a cylinder of stout paper. The end of the paper tube dips into a receiver nearly full of water, which, again, rests on a ring of straw placed at the bottom of a larger vessel, also filled with water. The heat being assisted by wood and a chimney, now causes the mercury to boil, and its vapour, condensing, rolls down the paper tube and collects in the receiver. As soon as it is cold, the water is poured off, and any trace of iron, or of oxide of mercury, which generally appear as a thin film, is readily removed by hydrochloric acid. The mercury is then well washed in water, dried at a gentle heat, or run through bibulous paper till it ceases to damp it; after which it may be passed through a cone of writing paper, having a very small aperture, which removes all traces of mechanical impurity. Or, instead of glass, a wrought-iron mercurial bottle may be employed. This bottle should never be more than half full, and must be fitted with an iron delivery tube, to the end of which a canvas pipe is attached, on which a jet of water is directed; the condensed mercury falls into a vessel. A second method is by treatment with strong sulphuric acid. This is best effected by covering the metal with its own volume of concentrated oil of vitriol in a flat glass or porcelain dish, stirring repeatedly with a glass rod, and leaving the metal and the acid in contact for six or seven days. Pure mercury, as has been already said, is not attacked by this acid, and digestion in the cold has merely to be repeated with successive portions of oil of vitriol as long as sulphurous gas is given off, or the liquid shows any symptoms of turbidity. It is certain that by this process even lead may be removed, although, under ordinary circumstances, that metal is but little attacked by strong cold sulphuric acid. But, in the first place, the lead in this case is in the form of amalgam, which implies minute subdivision of its particles, and at the same time the tendency of the acid towards the lead appears to be increased by the presence of the mercury. Such metals as gold, silver, and platinum, which are not acted on by sulphuric acid, cannot, of course, be separated from mercury, except by distillation.

A third method is to heat the metal for several hours to 130° , with a small quantity of commercial nitric acid diluted with twice its volume of pure water. The foreign metals being more easily oxidised than the mercury, are dissolved, and this operation having been repeated as often as required, the purified metal is then washed and dried.

A solution of nitrate of mercury may be substituted for one of nitric acid. In this way an equivalent of metal is deposited for every equivalent of more oxidisable metal which is removed. These nitric processes

are, however, liable to this disadvantage, that the foreign metals can only be completely removed when some mercury remains in solution.

The process recommended by MELLON, and which REGNAULT employed to obtain pure mercury for his third determination of its density, is as follows:—He first agitated the metal for some time with weak nitric acid, using for two pounds of mercury an ounce and a half of acid and two ounces of water. By this means all the more oxidisable metals were acted upon. The solution containing these having been poured off, the mercury was again digested with strong nitric acid, till nine-tenths of it was dissolved. The resulting nitrate was converted thereafter into mercuric oxide, which, in its turn, was changed by heat into the metallic form. All traces of oxide having been removed by agitation with strong oil of vitriol, the product was carefully washed and dried *in vacuo*.

Dr. PRIESTLEY gives, in his *Observations on Mercury*, a simple process by which effectually to separate quicksilver from lead and tin. He employed continued agitation, with fresh portions of air supplied by repeatedly blowing into a small glass phial, in which the mercury was actively shaken. A little powdered sugar very much assists this process, by mechanically collecting and retaining on its particles the portions of foreign oxides as they are produced. The fluid metal may then be run through a cone of paper, having a very minute aperture at the bottom, by which all the solid particles, including dust, fibres, *et cetera*, are retained.

Other methods might be resorted to, such as the decomposition of the factitious cinnabar by heat and iron filings, or of the commercial red precipitate alone by heat, with the subsequent removal of all adhering oxide, by means of sulphuric acid. Or the metal may be sublimed along with one-tenth of its weight of powdered vermilion; or, according to the method of ULEX, two pounds of mercury may be agitated with half an ounce of solution of sesquichloride of iron; specific gravity 1.48. Ten minutes suffice to remove all metallic impurities of the ordinary kind, a result which the finely divided state of the metal seems to favor. Lastly, VIOLETTE proposes to make use of highly-heated steam. It is a well-known fact that when this metal is boiled with water in a flask, mercurial vapor rises, and is carried off with the steam. The distillation of mercury by the method of VIOLETTE has especial reference to its removal from silver in smelting houses. The process is said to effect a considerable saving of fuel, and of the health of the workmen. It is performed by bringing the steam up to 700°, in its passage through a worm, from which it enters the vessel containing the mercury, dipping a little way beneath its surface, and soon causing the metal to boil; after which the mercurial and aqueous vapors are carried off, and suitably condensed.

It may be here remarked that pure mercury is entirely volatilized in the heat; it dissolves completely in nitric acid, producing a nitrate of the metal, which, when the acid is employed in excess, is easily soluble in water. Poured into a narrow glass vessel, it presents a convex surface, owing to the mutual attraction of glass and mercury being at best but feeble; if, however, the

metal be amalgamated with as slight a quantity as the one four-thousandth part of lead, the convexity of the pure metal is destroyed, and the surface becomes even.

Physiological Effects.—It has long been a matter of doubt and discussion whether this metal exercises any physiological effects upon the human system, analogous to those of most of its saline compounds. It is generally admitted that, when taken in compact masses, the metal does not exert a poisonous action, although it may occasion injury mechanically; but when in a finely attenuated state, as in vapor, or *deadened* with innocuous substances, it possesses the power of manifesting all the symptoms of a mercurial poison.

All the effects of mercurial poisoning are very frequently observed among the miners and smelters of this metal, as also in those who work with water-gilders, looking-glass and barometer makers. For the most part they appear as the disease known as the *mercurial trembling*, or a kind of palsy, which first manifests itself by an unsteadiness in the arms, and which goes on till the movement becomes convulsive, and vertigo, loss of memory, and other cerebral disorders, which generally terminate fatally, follow. When the symptoms develop themselves in a mild form, and the individual perseveres in his labors, they proceed, and never fail to become more violent, and endanger the life of the person. This is well known in the mercurial mining and smelting districts, where if once a man becomes affected with trembling or salivation he is removed to a less dangerous department, or disbanded altogether. Some physiologists have remarked that the circulation is usually depressed and slow when the patient is undergoing salivation, and exhibits other symptoms of the effects of mercury; whilst others have observed an excited state of circulation, a fetid breath, with metallic taste in the mouth, increased flow of saliva, and a sponginess of the gums proceeding to ulceration, which sometimes extended to the throat.

Vegetal physiologists state that mercurial vapor is destructive in a high degree to the life of plants.

MERCURIAL COMPOUNDS.—Mercury is capable of combining with most of the non-metallic elements, and many of the compounds thus formed are capable of constituting ingredients in further combinations; it has, therefore, a wide range of affinity, but in a manufacturing sense most of those compounds are unimportant, although in a strictly scientific point of view, and also on account of their medicinal qualities, they sometimes attract a great deal of attention. The principal compounds of mercury to be considered here are the sulphide—*cinnabar*, *vermilion*—the chlorides, oxides, iodides, *fulminating mercury*, and the ammonio-mercurial chloride known as *white precipitate*. The oxides, though not the most important, will be noticed first.

OXIDES OF MERCURY.—As stated already, there are two oxides of mercury, the *sub* and *prot*-oxide, which are capable of yielding well-defined salts of the respective bases. The first of these is not so stable as the second, nor is it so important in its applications.

Suboxide of mercury was first scientifically described in 1797; but was known, probably, long before that period as the *æthiops per se* of the pharmacæutists. There are several methods for preparing it; the

simplest and readiest being the precipitation of a dilute solution of a subnitrate of mercury by potassa; or it may be formed by disseminating calomel in water, and adding a proportionate quantity of potassa to the liquor, when suboxide of mercury falls. The change may be expressed thus:—

Or,

All the operations connected with this compound should be performed out of diffused daylight; and care must also be taken that the precipitation be complete, otherwise the substance thrown down will consist of a mixture of suboxide, protoxide, and metallic mercury.

After being thoroughly washed, to remove alkalinity, and dried in the dark, suboxide of mercury is a black powder, having a disagreeable odor—GMELIN says it is devoid of taste and smell—it is insoluble in water and alkalies, soluble in nitric and acetic acids, and has a specific gravity of 10.6, HERAPATH; 8.95, KARSTEN. It is very rapidly decomposed, when exposed to the light of the sun, into protoxide and metallic mercury; but the same change, though slowly, is effected in the darkness. Heat resolves it into oxygen and metal. It is also decomposed by many compounds, the mercury being taken into other states of combination, and sometimes set free. Its composition is expressed centesimally by

	At. weight.	Donovan.	Guibourt.

The suboxide of mercury is converted to no particular use in the arts.

Protoxide of Mercury.—This is the *precipitatum per se*, or calx of mercury, mentioned in old writings; it is analogous to the *hydrargyri oxidum rubrum* of modern pharmacy. Protoxide of mercury has an interest attached to it much greater than its application in the arts would merit, owing to the knowledge of its nature and composition being contemporary with the discovery of oxygen, the subversion of the old phlogiston theory, and the introduction and pursuit of a new and more enlightened system of chemical science. It was formerly prepared by submitting mercury to a high temperature in a narrow-necked flat-bottomed matrass, known as BOYLE'S *hell*, when, after a long period, the metal was slowly converted into oxide. This process is now, however, quite abandoned; salifying the metal, and subsequent precipitation of the oxide, being considered more effectual. One part of mercury is treated with three parts of nitric acid, specific gravity 1.20, in a flask on the sand bath, till perfect solution takes place, and the solution evaporated to dryness, the residue mixed up with another part of the metal, and the whole heated again as long as nitrous fumes are

observed to pass off. The residue, which now appears a dull grey mass, is removed from the heat, mixed with a tenth of its weight of pure crystallized carbonate of soda, and the whole boiled with water for a quarter of an hour, when impure protoxide of mercury settles to the bottom, and this by filtration and washing may be converted into pure protoxide—*red oxide of mercury*. The nitrate of mercury alone may be submitted to heat in this operation, but a loss of nitric acid would take place; besides, the degree of heat is critical, so that it is more productive and less troublesome to proceed as above stated. By the following formula the changes of the substances here alluded to are expressed:—

And secondly—

Oxide of mercury prepared by the action of heat upon a protosalt of the metal, forms a shining brick-red crystalline scaly powder, which, on being pulverized, acquires an orange tint. By the action of a moderate heat it changes to a vermilion color, which passes as the temperature rises to a darker hue, approaching to black, but as the substance cools the natural shade is regained. The specific gravity of the red powder has been variously estimated, the number arrived at by PLAYFAIR and JOULE being 11.136. It is but slightly soluble in water, only one part being taken up by seven thousand parts of this liquid; the solution, however, has a disagreeable metallic taste, and exhibits an alkaline reaction to delicate color tests; but alcohol fails to dissolve it. Between 700° and 900° it is resolved into its elements. Oxide of mercury obtained by precipitation is an amorphous yellow powder, and in this differs from that obtained by heat. There are also many other reactions wherein they behave differently.

The protoxide is readily decomposed by several substances; even light is capable of resolving it into mercury and oxygen gas; heat, and all organic substances, produce the same effect, only much more quickly. On this account it is frequently employed by the analyst to remove the last traces of carbon from a substance, and to oxidise sulphur into sulphuric acid. Phosphorus, sulphur, sulphurous acid, the alkali metals, protochloride of tin, and several other bodies, decompose it, many of them with evolution of light and heat. The protoxide of mercury may be distinguished from the suboxide, first by its color, and secondly by its solutions not giving a white flocculent precipitate with hydrochloric acid; it also produces, with solutions of hydriodic acid, or of alkaline iodides, a beautiful scarlet precipitate of iodide of mercury, and which is characteristic compared with the dull green color of the subiodide. Potassa gives a yellow, and ammonia a white precipitate, both of which are sufficiently distinct from the black deposit that they afford in solutions of the suboxide of this metal.

Protoxide of mercury is composed of—

		Centesimally.			
	At. weight.	Theory.	Donovan.	Erdman and Marchand.	
1 Eq. of mercury,....	100 ..	92.59 ..	92.75 ..	92.596	
1 Eq. of oxygen,....	8 ..	7.41 ..	7.25 ..	7.404	
	108	100.00	100.00	100.000	

Its chemical symbol is Hg O.

It is stated that protoxide of mercury is occasionally adulterated with minium or red lead, sesquioxide of iron, and powdered brick. Such substances are readily detected by heating the substance to a dull heat; the protoxide of mercury sublimes, and leaves the non-volatile matters in the crucible, or the mercurial compound may be treated with dilute nitric acid, to dissolve the mercurial oxide; and should minium be present, a puce-colored binocide of lead remains together with the other adulterants, if any be present. On adding dilute sulphuric acid to the clear liquor obtained in the foregoing, a white precipitate of sulphate of lead falls, corroborative of the existence of a lead compound.

SULPHIDES OF MERCURY.—Sulphur and mercury are capable of uniting artificially, and of forming compounds analogous to those produced from this metal with oxygen.

The *subsulphide* is the *æthiops mineral* of the older chemists, and was prepared by agitating a little water, sulphur, and mercury, in equal proportions, in a mortar, or at a slightly increased heat, till a black powder resulted. It can be obtained by transmitting a stream of sulphide of hydrogen gas through a dilute solution of subnitrate of mercury in the cold, when a subsulphide of a black color falls. The reaction is as follows:—

Heat must be guarded in this operation, since it would resolve the subsulphide into a protosulphide of mercury and metal, thus—

Prepared by either method, this compound appears as a black, tasteless, inodorous powder, which is insoluble in water, in hydrochloric, and dilute nitric acids. By heat it is resolved into mercury, and the red sulphide of the metal—cinnabar. Its chemical composition is—

	At. weight.	Centesimally.
2 Eq. of mercury,.....	200	92.59
1 Eq. of sulphur,.....	16	7.41
1 Eq. of subsulphide of mercury,	216	100.00

This compound is not prepared in any quantity, nor has it any application, excepting among veterinary surgeons, and even these are abandoning it for more appropriate agents.

Protosulphide of Mercury.—*Cinnabar, Vermilion.*—

This is a much more important compound, though, like the former, medicinally inert. The character and composition of the native ore have been already explained. Only a small quantity of that mineral, however, is of sufficiently fine quality to permit of its being employed as a pigment. Chemically, there is no difficulty in forming it;

but its value in the arts depends upon the richness of its color, the exact conditions to insure which are far from being generally understood. The following are some of the processes for its preparation:—

When sulphide of hydrogen gas is passed to saturation through a solution of protoxide of mercury, the white compound which appears at an early stage of the operation is destroyed, and the black precipitate then consists solely of mercuric sulphide, which, when collected, dried, and heated in a retort, yields a fine crystalline sublimate of cinnabar. These two bodies, therefore, the black and the red, are allotropic modifications of one substance, Hg S.

The process of LIEBIG consists in forming the *white precipitate* Hg Cl, Hg N H₂, and digesting it with sulphide of ammonium, obtained by saturating the common alkaline hydrosulphide with sulphur. The color of the product he afterwards improves by boiling with caustic potassa.

KIRCHOFF recommends triturating one hundred parts of mercury in a porcelain dish, with twenty-three parts of flowers of sulphur, chemical action being assisted from time to time by moistening the mixture with solution of caustic potassa. A potassa lie, containing fifty-three parts of solid hydrate in fifty-three of water, is next prepared, and in it the sulphurised mercury is warmed, and further triturated. The water must be replaced as it evaporates, and the operation continued for two hours. After this, and still with trituration, the red mass is evaporated to a thin paste, removing the heat at the moment when the red color has attained its finest shade; for a few seconds, either too soon or too late, deteriorates the quality of the product. Too little heat fails to bring up the red to its utmost degree of brightness, and a little too high, or even too long continuance of the proper temperature, changes the color to brown, and it can never be restored. The product, when cool, is *first* washed with a solution of potassa, and *afterwards* with water.

URE, in alluding to the process of KIRSCHOFF, remarks that of late it has been so much improved that the vermilion which it yields quite equals in tint that made in China. It appears also by the following table, that the quantity of vermilion which can be obtained, depends on the relative proportion of the substances employed:—

Mercury.	Sulphur.	Potassa.	Vermilion.
300	114	75	330
—	115	75	331
—	120	120	321
—	150	152	382
—	120	180	245
—	100	180	244
—	60	180	142

BRUNNER directs the trituration of one hundred parts of mercury with thirty-eight of sulphur. The *æthiops* so produced is next heated to 113° with twenty-five parts of potassa in one hundred and thirty-three to one hundred and fifty parts of water, and more liquid supplied as it becomes reduced by evaporation, the mixture being kept occasionally stirred. After a few hours the black substance begins to take a brown tint, and if the heat be maintained at 113° to 118°, this goes on brightening till it becomes a lively red. Whenever the mixture becomes

gelatinous, more water must be added, for it is absolutely necessary for the success of the process that it be kept in as pulverulent a state as possible, and also that the heat rise not above 120° to 122° . When the product has attained the fine red required, and which happens in the course of eight hours, the fire is removed, and the contents of the vessel are left to cool slowly. The cinnabar is then removed, washed with water, and further purified by levigation from any mercury or black sulphide which might still remain. BRUNNER states that one hundred parts of mercury, forty parts of sulphur, and forty of potassa, afford one hundred and seven parts of vermilion little inferior to the finest native substance, and much superior to any obtained by sublimation.

Dutch Method of Making Vermilion.—It is well known that the monopoly of preparing this pigment was long held by the Dutch, who alone, at one time, possessed in Europe the secret of giving to it a rich scarlet color. The particulars of the old method of its preparation at Amsterdam were many years ago described by M. TUCKERT in the *Annales de Chimie*. The process consisted of two parts; first, the production of what M. TUCKERT terms æthiops, but which is a mixture of cinnabar, black sulphide, uncombined metal, and sulphur; and, second, the conversion of this into the pure vermilion.

The first part of the operation was to effect the combination in a flat polished iron pot, two and a half feet in diameter, and one deep. Into this, one thousand and eighty pounds of mercury and one hundred and fifty pounds of sulphur—equivalent to 87.8 of mercury and 12.2 of sulphur, per cent.—were introduced, and the mixture stirred with an iron spatula very cautiously, because if the components were too briskly mingled, the combination would be too violent, and some of the substances would be lost. The black product of this operation, being reduced to powder, was next placed in hand jars capable of holding one pound and a half of water—thirty to forty of them being constantly kept full. The subliming pots, three in number, which were made of pure sand and clay, and well luted outside, were each covered with a smooth iron lid, and placed in a furnace secured with hoops of iron; the position of the pots being such that the flame could play over two-thirds of their height. In the evening the operation of heating the pots was begun, and as soon as they attained a red heat the iron covers were removed, and a pipkinfull of black sulphide thrown into each, and there left to crackle and burn. This emptying of the smaller pots into the larger was continued—sometimes two or more being emptied into the subliming pot at once, till, in the course of thirty-four hours, four hundred and ten pounds had been emptied into each of the three. As each fresh portion of black matter was thrown in, the mixture took fire, and the flame rose from three to six feet above the edge of the pot. During this period the cover was not replaced; but as it subsided the pot was again covered with the iron plate, until it was necessary to remove it for the introduction of more sulphide. For thirty-six hours after the last portion was added, the same steady heat was continued, and the contents of the pot occasionally

stirred by means of an iron rod which passed through the top of the lid. During this period, also, the workman tested from time to time the security of the process, by cautiously removing the pots, and observing to what height the flame then rose, and with what vigor it burnt. The proper temperature was indicated by a vigorous combustion, accompanied by a flame, which did not rise more than three or four inches over the edge of the pot.

When the thirty-six hours were expired, the whole was allowed to cool, after which the pots were removed and broken, and the vermilion which was incrustated within them, and chiefly in their upper parts, collected, ground with water between horizontal stones, then passed through sieves, and thereafter elutriated and dried. The usual loss in converting the black sulphide by this process into vermilion, was nearly three per cent.

Method adopted at Idria.—At Idria, as already stated, large quantities of the sulphide of mercury pigment are annually prepared. The method pursued is to introduce into a number of well-bound casks, contrived to turn on their axes, eight pounds of sulphur and forty-two of mercury, and then to put them in motion for three hours or more, till the ingredients combine to form a brownish powder. A number of cast-iron cylinders, placed upright in a furnace and heated to dull redness, are then charged with this product, one hundred pounds being portioned to each, the weighted cast-iron cover being immediately fixed on, and retained till all crackling noise subsides. When this happens, the iron top is removed, and another of stoneware, having the beak connected with a tube and receiver substituted; at the same time the fire is increased for the purpose of expelling the sulphide of mercury from the iron cylinder. After the sublimation of the charge, the capital and tube are removed, and when cold, the cake of cinnabar is separated. That which has the brightest tint is found caked on the outside of the cover; the portion collected in the tube and receiver is generally mixed with an excess of sulphur, which volatilizes with it, and for the most part is returned with a fresh charge of æthiops to be re-sublimed. The cakes of cinnabar are broken, and ground finely with water; then boiled with a solution of potassa, washed first with hot, and next with cold water, and finally dried.

Chinese Vermilion, which is so rich in color as to command five or six times the price of the European product, appears to be prepared in the ordinary way, leaving nothing to account for the superior brilliancy of shade except the sunnier climate. By careful selection, the finest portions are collected, and, if necessary, ground and washed several times. In making the artificial product, one part of sulphur and four of mercury are introduced into an earthen pot, to which an iron cover is luted and bound with wire; the pot with its contents is then placed in a fire of dried camel's dung. After sublimation, the cover is removed and the pot broken, and the purest of the sublimed picked out from the less-colored product, ground very fine, and the powder sifted into a large vessel of water. When the red product has subsided, the supernatant

water and scum are drawn off, and fresh liquid supplied, in which the sediment is stirred up, and after subsidence, the substance is collected and carefully dried in the sun.

By subliming one part of sulphide of antimony with sulphide of mercury, a greyish cinnabar is obtained. On boiling this with a solution of *liver of sulphur*—a compound of sulphur and potassium—and afterwards with hydrochloric acid, and washing thoroughly with water, a product is obtained which is quite as brilliant as the finest Chinese vermilion, and retains no antimonial sulphide. Sulphide of mercury prepared by saturating a solution of oxide of mercury, is a black substance, but when prepared by the other processes mentioned, it has a red color, more or less lively. It is a soft, heavy, colorless, and tasteless powder if prepared by the moist method, and is devoid of crystalline structure, but the sublimed product appears in masses composed of hexahedral needles. Exposed to the light of the sun it gradually acquires on the surface a grey tint, owing to a portion being decomposed into mercury and sulphur.

Properties.—Water or alcohol have no action upon cinnabar. Cold hydrochloric and nitric acid singly fail to dissolve it; but nitro-hydrochloric acid readily attacks it and converts it into chloride. Nitric acid, when heated, decomposes it, and produces a protosulphate of oxide of mercury and sulphur. Caustic potassa or soda in solution does not decompose cinnabar; but if the hydrate of the alkali be employed, and its action be assisted by increased temperature, decomposition takes place, which results in the production of metallic mercury, sulphate and sulphide of the alkali.

A temperature approaching a red heat volatilizes it without decomposition; if air be admitted the sulphide burns, the sulphur being converted into sulphurous and sulphuric acids, and the metal disseminated in the vapor. Charcoal, and other carbonaceous matters, iron filings, lime, or any of the fixed alkaline bases, also abstract the sulphur and set the metal free.

Cinnabar is composed centesimally, according to the analyses of PROUST and GUIBOURT compared with theory, as follows:—

	At Weight.	Theory.	Proust.	Guibourt.
1 Eq. of mercury,.....	100 ..	86.21 ..	85.0 ..	86.21
1 Eq. of sulphur,.....	16 ..	13.79 ..	15.0 ..	13.79
1 Eq. of sulphide of mercury, 116	100.00	100.0	100.0	100.00

These determinations lead to the formula Hg S.

Cinnabar or vermilion is principally employed for its hue, and is but rarely prescribed by the physician. Its high price exposes it to considerable sophistication in the hands of unprincipled traders. The adulterations which are most likely to be contained in it are minium or red lead, ferro-ferric oxide, Fe_3O_4 , red brick dust, and pentasulphide of arsenic. In searching for red lead in this case, the same directions as those given for the detection of the same adulterant in red oxide of mercury may be pursued; brickdust may likewise be detected in the way there directed; iron may be readily found by treating the residue, after the sublimation of the mercurial sulphide, with hydrochloric acid, and

testing the filtered liquid with ferrocyanide of potassium—yellow prussiate—when a blue precipitate will appear if iron be present. Pentasulphide of arsenic may be found by treating the pigment repeatedly with strong solution of potassa, boiling, filtering off the liquid, adding to it hydrochloric acid, with a few fragments of zinc or iron, and, subsequently, transmitting sulphide of hydrogen gas through the solution, then boiling, filtering off the liquid, and adding hydrochloric acid to it to saturation. After some time sulphide of arsenic of a yellow color falls. In this case the alkali dissolves the quinesulphide from the mercury compound, and the hydrochloric acid again effects its precipitation.

The pigmentary uses of cinnabar are not confined to its external application in painting. It is largely consumed in the manufacture of red sealing wax, in which it is mixed up with venetian turpentine, shellac, and colophony. It is also employed in coloring wafers, and has been for the same purpose used in confectionary, and to improve the color of cayenne pepper; a practice greatly to be reprobated, for although Mr. TAYLOR states that he has not been able to find any instance of its having acted as a poison on man, yet thirty to seventy grains, even applied externally, have proved poisonous to the lower animals. It can scarcely be said to be used medicinally at the present time, though in 1769, Dr. DALBY wrote a book in praise of the virtues of cinnabar and musk in the cure of hydrophobia. BOLLEY proposes a solution of the ammonio-nitrate of silver as a test for cinnabar, for with whatever other matters it may be mixed up as a coloring matter, an instantaneous black color is produced, resulting from the formation of sulphide of silver along with basic nitrate, and also amide of mercury.

CHLORIDES OF MERCURY.—It may be safely stated that of all the compounds of mercury, none are of greater importance, in a medicinal point of view, than the two compounds produced by the union of chlorine and mercury, and which are well-known by the title of *calomel*—subchloride of mercury—and *corrosive sublimate*—protochloride of mercury. It is the growing opinion that in whatever state of combination mercury is administered by the medical practitioner, the active effects are the result of the chlorides of the metal, these being formed by the chlorides and free hydrochloric acid of the stomach. The experiments of MAILHE tend to corroborate this view, and hence the two compounds of mercury and chlorine are the principal mercurial combinations to which attention is directed in the several pharmacopœiæ of the medical colleges. For this reason, various methods are given for their preparation, and also for ascertaining their purity.

Subchloride of Mercury—Calomel.—As stated under the ores of mercury, this combination is met with in several mines in the form of incrustations—horn quick-silver—on other ores, or disseminated in the form of small transparent and translucent crystals. Those mines where it is particularly noticed, are the Almaden, Idria, Moschellandsberg; the mines of the Palatinate, Deux Ponts, and Bohemia. The quantity so found is, however, unimportant, and the native substance is never applied in medicine, that which is artificially prepared being preferred. There are several methods by which subchloride

of mercury may be obtained, as well by precipitation as by the dry way. When a solution of pure subnitrate of mercury is precipitated by another of a pure alkaline chloride, or with dilute hydrochloric acid, a white flocculent mass falls, which is the compound in question, and when washed well and dried it is chemically pure. It is necessary, however, to prolong the washings, otherwise some traces of the alkaline precipitant are retained, which react as a solvent upon a part of the precipitate by forming a double compound with it; and hence it is that calomel prepared in this way always leaves a mercurial taste. To guard against this, recourse is usually had to the dry method, in which the mercurial subsalt and chloride of sodium are mixed in the proper proportions, and then submitted to heat in a subliming pot, when the calomel is obtained in the form of a white incrustation on the cover of the vessel. Prepared in either way subchloride of mercury is a yellowish-white powder, which under the influence of solar light turns grey, being transformed into the protochloride and metallic mercury; it is but very slightly soluble, one part of the salt requiring twelve thousand of boiling water for perfect solution. Dilute hydrochloric acid has no action upon it, but when concentrated it changes the salt into metal and protochloride, thus—

Concentrated boiling solutions of the fixed alkaline chlorides, and of chloride of ammonium, react upon calomel in the same way. Hot strong nitric acid readily dissolves the subchloride of mercury, converting it into a protonitrate and protochloride of the metal. It is readily sublimed, and forms crystals on condensing. Its applications are chiefly medicinal, but it is employed in the laboratory as a test, though not frequently so used.

The symbol for this salt is $\text{Hg}_2 \text{Cl}$, corresponding with the suboxide Hg_2O ; its atomic weight, $100 + 35.5 = 135.5$; its density, 59.77 .

The formula given above agrees with the following composition:—

Centesimally.				
	At. weight.	Theory.	Klaproth.	
2 Eqs. of mercury,....	200	84.96	85.10	
1 Eq. of chlorine,....	35.5	15.04	14.90	
	235.5	100.00	100.00	
Volume.				
Mercurial vapor.....	1	=	6.9300	
Chlorine.....	$\frac{1}{2}$	=	1.2271	
Vapor of calomel.....	1	=	8.1571	

Although CHRISTISON and other authorities assert, that the calomel prepared by precipitating a dilute solution of a subsalt of mercury with one of chloride of sodium in the manner already stated, or by agitating a solution of sesquichloride of iron with metallic mercury, does not differ in therapeutic properties from that formed by sublimation, still the latter method

is adopted in the manufacture. Various recipes are known for obtaining it; thus, by mixing four parts of corrosive sublimate—protochloride of mercury—with three parts of the metal, and subliming, calomel is obtained; likewise, when sulphate of the protoxide of this metal is heated with an equivalent proportion of common salt and mercury, corrosive sublimate is produced. In the first instance the reaction may be symbolized thus—

and in the second,

When operating according to the first equation, it is required to have the metal in slight excess, in order to insure the complete reduction of the protochloride. MOHR states that this method is frequently adopted in the German pharmaceutical laboratories. The materials are ground up with a little water, or spirit, to prevent the escape of dust or powder, and when the metal is *deadened* the material is placed in glass vials and heated; after sublimation the product is collected by breaking off the neck of the bottles, and detaching the crust of salt.

When preparing it by the second method, which is much the better of the two, two parts of mercury are dissolved in three of strong sulphuric acid, or better still, four ounces of the metal are acted upon with two ounces two drachms, liquid measure, of strong sulphuric acid, to which half a fluid drachm of strong nitric acid is added.

When sulphuric acid only is employed, the sulphate of mercury obtained by evaporation is mixed with two parts of metal, and afterwards with one part and a half of common salt, the whole being triturated in a mortar till the metal disappears. The mass is then sublimed in the usual way. In this operation the whole of the mercury is, however, never reduced to calomel, and on this account the sublimed mass requires purification from corrosive sublimate by repeated washings with boiling water, in which the latter is freely soluble. As soon as the washings give but faint indications of precipitates with a solution of nitrate of silver or sulphide of hydrogen gas, the calomel may be considered pure.

Fig. 366 is a drawing of a subliming apparatus described by MOHR. It consists of an earthenware tube, *b*, one foot long and a little more than two inches wide. This tube passes through a small furnace, and is connected on the left with a small bellows, and on the right with the wider pipe, *e*, that enters the box or chamber, *d*, where the sublimed calomel collects. This box is lined interiorly with glazed paper, the top being secured by a cloth, *m*, which is retained in its place by the funnel-cap, *e*, terminating in the chimney, *f*. At *g* is shown a small iron gallery for retaining hot charcoal, by which means a continuous draught is maintained.

The fire having been laid on at *a* and *g*, and as soon as the temperature rises to the subliming degree, air is urged through the apparatus by working the bellows, and this forces the calomel vapors, as fast as they rise,

Fig. 366.

into the chamber, *d*; as soon, however, as the chimney has become sufficiently hot by the chauffer in it, the blowing apparatus may be detached, as there will then be sufficient draught to carry the sublimed vapors into the receiver without mechanical aid. As the charge already in the tube, *b*, becomes exhausted, a further quantity may be introduced at the open side, and as long as the fire in *g* remains, the current of air drawn through will be sufficient to prevent any mercurial vapor escaping by the open end.

Under ordinary circumstances the incrustated calomel requires to be finely ground before it is fit for use. This operation is generally performed under lead rollers, unless the salt be minutely subdivided at the moment of condensation. Mr. JEWELL, patented a process for effecting this, which has since been improved by M. O. HENRY and SOUBEIRAN, and consisted in allowing the mercurial vapor to pass into a vessel charged with steam, having water in the bottom. By this arrangement the substance becomes reduced to the finest state of division.

Thomson's Gaseous Method.—A patent was sealed on the 8th March, 1841, by Dr. ANTHONY TODD THOMSON, for manufacturing the chlorides of mercury by the direct union of the elements. It has long been known that even at common temperatures mercury and chlorine gas combine, though slowly, and that when heated the combination is effected rapidly with the development of heat and light. In Dr. THOMSON'S process the proportion in which the gas is admitted determines the nature of the product. The process is as follows:—A glass, earthenware, or other suitable vessel, provided with openings at both ends, is mounted in brickwork, or in any other convenient manner, and exposed to the action of an open fire beneath. A certain quantity of mercury is placed in this vessel, and the temperature raised to between 350° and 660°. One end of the glass communicates with an alembic, such as is generally used for generating chlorine gas, and the other end is connected with a large chamber made perfectly air-tight, to prevent the escape of any of the gases. In order to procure the chlorine, the alembic is charged

with a mixture of common salt, binocide of manganese, and sulphuric acid. The chlorine gas, as it is generated, passes from the alembic through the bent tube into the glass or earthenware vessel which contains the mercury, when it combines with its vapors, generated by raising it to 350° and above. The combination of the two gases forms either calomel or corrosive sublimate according to the quantity of chlorine gas employed. The product is found at the bottom of the air-tight vessel, from whence it may be taken after the operation is completed.

The patentee claimed the direct combination of the gas, not only with the mercurial vapor, but with the metal in any form.

Properties of Calomel.—The form in which calomel sublimes is modified by the dimensions of the apparatus employed, and the temperature at which it is produced. Prepared in small vessels it usually takes the shape of a fibro-crystalline cake, which when powdered is yellow or buff, whereas if the apparatus is large, and the receiver cold, it falls as a white impalpable powder. The crystals of calomel are square prisms, Fig. 367, with a specific gravity of 7.150; 7.156, PELOUZE and FREMY; 6.9920, KARSTEN. Calomel is not volatile at ordinary temperatures. Below a red heat it sublimes without fusing. It has neither taste nor smell, and is insoluble in pure water at 60° Fahr. Boiling muriatic acid quickly changes calomel into corrosive sublimate and metallic mercury. In hot nitric acid it dissolves, evolving nitric oxide. In the cold, sulphuric acid neither dissolves nor decomposes it, but the action of hot sulphuric acid is to produce the higher chloride, a sulphate of mercuric oxide, and sulphurous acid gas, thus—

Fig. 367.

Solutions of the fixed alkalis convert it into black oxide, and by ammonia it is changed into the double salt, 2 (Mg NH₂), Hg₂ Cl, which is also black. This amide compound is different from that which is formed when calomel and dry ammonia are brought in contact; the last has, according to KANE, the formula 2 Hg₂ Cl, H NH₂.

The trade adulterations of calomel are chalk, sulphate of baryta, carbonate of lead, common salt, sal ammoniac, and sometimes a little corrosive sublimate. For the detection of all impurities, the Edinburgh college directs that heat, sulphuric ether, and solution of caustic potassa should be employed. Calomel, if pure, is entirely volatilized by heat, all fixed impurities will therefore be found in the residue, whilst the sublimate may contain, besides calomel, the mercuric chloride and sal ammoniac. These impurities being soluble in water,

a solution is readily obtained containing both, and this liquid, when acted on by aqua potassæ, gives a yellow precipitate or cloud; after which, if gently heated, fumes of ammonia will be given off, producing, in contact with muriatic acid, the white vapors of muriate of ammonia. Or the liquid may be gently evaporated, and the solid residue treated with solution of caustic potassa, after which the volatile ammonia may also be brought in contact with the hydrochloric acid vapor.

The fixed residue supposed to contain barytic, sulphate, white lead, and chalk, may now be treated with pure and dilute nitric acid; any insoluble matter still remaining is set aside for examination, and the solution in nitric acid, which, if it was attended with effervescence, showed the presence of carbonic acid, may be, if necessary, diluted with water. Solution of sulphide of hydrogen gas is then added, and a black precipitate obtained, if lead be present. The clear liquid filtered from the plumbic sulphide is next neutralized by ammonia, and oxalate of ammonia added. A white precipitate proves the presence of lime.

Returning now to the insoluble residue from the nitric solution, which may still contain sulphate of lead and sulphate of baryta—the solid matter may at once be tested with a drop of sulphide of ammonium. If lead be present, it will be immediately blackened. If otherwise, then having been well washed with water, it may be boiled with pure carbonate of potassa, the solution filtered, excess of alkaline carbonate in the liquid expelled by pure hydrochloric acid, and afterwards chloride of barium added to detect the presence of sulphuric acid. If a white precipitate is observed, then the white matter left on the filter is carefully washed and dissolved in a small portion of pure hydrochloric acid; to this liquid dilute sulphuric acid is next added, and a precipitate of sulphate of baryta is obtained.

It is well known that calomel boiled with water, very slightly acidulated with hydrochloric acid, and containing a slip of clean copper, gives a deposit on that metal of metallic mercury. In the case of a solution of corrosive sublimate, the same test may be employed, or the following neat arrangement may be adopted:—A drop of the liquid is placed on a sovereign, and an iron key is placed so that one part is immersed in the liquid whilst another touches the gold of the coin. At the former point a brilliant mercurial stain is immediately produced by the galvanic current. A copper coin may take the place of the gold, in which case a strip of clean zinc, slightly arched, must be substituted for the iron key.

Finally, it being established that the solution contains mercury, the identification of it, as the bichloride, may be easily effected by solutions of nitrate of silver, caustic ammonia, iodide of potassium, and protochloride of tin.

Medicinally, calomel is the mildest and most generally employed of all mercurials. It is irritant, however, in large doses, and to some constitutions, violently so. In small doses, and especially when combined with opium, it is sedative and antiphlogistic. Even alone, it possesses a cathartic action; but this, like the pre-

ceding, is rendered more certain by combining it with evacuants, as jalap and colocynth. Combined with digitalis or squills it is an effective diuretic, and its diaphoretic, like its sedative properties, are best developed in combination with opium. Its alterative properties are most generally produced by the use of small doses daily, or it may be given along with the golden sulphide of antimony, as *Plummer's pill*.

The Editor trusts, however, that before many years are over, medical men will have abolished the administration of all hydrargyric compounds, which can only have a baneful effect upon the system.

Protochloride of Mercury.—Corrosive Sublimate.—This combination of mercury, though containing the same elements as the last described compound, has very different properties, and, in a medical point of view, is much more active. It has been known from time immemorial, though the first description of it was given by GEBER of Thus, in Persia, who lived in the ninth century; and it has occupied ever since a prominent place in the *materia medica* of succeeding physicians. It may be prepared by acting upon the sulphate of protoxide of mercury by various metallic chlorides in solution—chloride of barium for instance—when a chloride of mercury is produced, together with a sulphate of the base of the precipitant. If the latter be insoluble, as in the case of baryta, the mercurial chloride may be obtained by evaporating the filtered liquor to dryness. Alkaline chlorides, chloride of magnesium, and other similar salts, effect the same changes, but slowly. By bringing together the vapor of mercury and chlorine gas, in the equivalent proportions, it is likewise produced.

None of these methods are, however, followed in its manufacture, recourse being always had to the dry process of subliming a mixture of chloride of sodium and sulphate of mercury, when a chloride of the latter and sulphate of soda are formed, the mercurial compound being expelled by the heat. Thus:—

Considerable quantities of this compound were prepared by the Dutch manufacturers before the knowledge of its formation became more general. Their mode of procedure was to mix equal parts of nitrate of mercury, decrepitated salt—chloride of sodium—and calcined or white martial vitriol—subsulphate of the sesquioxide of iron—and introduce the composition into a matrass, filling only one-third its capacity. The vessel was then imbedded in the sand bath, and heat applied till its bottom assumed a dull red, when a series of decompositions took place, by which chloride of mercury was produced and sublimed, whilst sulphate of soda and sesquioxide of iron remained in the matrass, and the nitric acid, after suffering decomposition, was evolved as nitrous acid, quadroxide of nitrogen— NO_2 —and oxygen. Another process was to cause metallic mercury, chloride of sodium, saltpetre, nitrate of potassa, and martial vitriol to react upon one another in the matrass by heat, when corrosive sublimate resulted.

GMELIN gives the rationale of this operation in the formula—

KUNKEL improved upon the process by producing first a sulphate of the protoxide of mercury, by acting on the metal with oil of vitriol, and heating in a matrass equal parts of this and common salt. Subsequently, FOURCROY, in order to dispense with the first operation, directed to employ sulphuric acid, mercury, and common salt, to submit the mass to heat, and finally to sublime it. In practice, the proportions taken were ten parts of mercury, eight of common salt, eleven of sulphuric acid, six of peroxide of manganese, and three of water. The decomposition in this case may be represented thus—

That is, there is formed, in the first instance, a sulphate of mercury by the concurrent oxidation of the binixide of manganese and the action of the sulphuric acid, and this sulphate is afterwards decomposed in the heat by the salt chloride of mercury being formed and expelled to the upper part of the matrass; sulphate of soda and protoxide of manganese being left in the bottom of the vessel.

The London college directs that one pound of mercury be boiled with thirty-one fluid ounces of sulphuric acid, and that the dry bipersulphate is to be mixed with half a pound of salt, and sublimed.

In the receipt of the Edinburgh college, the process for preparing calomel and corrosive sublimate is the same, with the exception that only half the quantity of mercury is taken for the latter.

The Dublin college at first prepares the sulphate of mercury, and intimately mixes this in fine powder with dried common salt, likewise ground, in the proportion of two of the former to one of the latter, subjecting the mixture to heat in an iron pot lined with clay, to which an earthen head is adapted. In either of these operations the temperature at which the salt is sublimed should not be too elevated, as in this case the chloride would fuse and fall back into the vessel, and thus occasion a loss.

In the formation of the sulphate of mercury, preparatory to subliming it with common salt, the materials are introduced into a cast-iron boiler, placed in brick-work, having a fire beneath it, and surmounted by a hood, to carry off the noxious gas evolved into the chimney. The heat required to effect the union of the mercury with the acid is moderate. In the course of the action, one portion of the acid is decomposed

into oxygen, and sulphurous acid, which escapes; the oxygen unites with the metal, and the oxide so formed, is salified by a second equivalent of sulphuric acid; the mass forms a thick magma, and continues to evolve sulphurous acid as long as any metal remains unoxidised. Some subsulphate is apt to be produced; but as it is necessary for the purity of the chloride which is intended to be obtained from this, to have the whole of the metal in the state of protosulphate, a quantity of acid should be employed at the end of the process, before the drying of the salt. The better to insure this, several tests may be made with a portion of the sulphate from time to time, by suspending it in water saturated with chloride of sodium; when the whole dissolves, it is evident that all the mercury is in the form of protosulphate; but should a white deposit be formed, it indicates that a sulphate of the suboxide still remains. When the sulphate is prepared, it is mixed with the requisite quantity of alkaline chloride, and a little binixide of manganese—one part to ten of the mercuric sulphate operated upon—and allowed to remain during two or three days, with the view of effecting a thorough decomposition. At the expiration of this period the fire is lighted, and a gentle heat maintained till all moisture has evaporated; after which, the mass is put into the sublimers, which may be of green glass, resting on cast-iron plates, and imbedded in sand up to the neck. In large factories, the subliming furnace is usually an oblong, capable of holding about one hundred matrasses, and heated by fires symmetrically disposed along the longer side. These are generally covered by a prismatic conical hood, from which a pipe leads into the chimney, with the view of carrying off any escaping vapors of the mercurial compound, and for which use, to be effectual, the chimney should have a good draught. The most important part of the business is the regulation of the heat, which, in the first instance, disengages moisture, and after this the mercurial salt begins to be volatilized. At this stage a small glazed conical vase is inverted on the neck of each matrass, in order to arrest any vapors which may make their escape. When white vapors are observed, it is a certain sign that the heat is too strong, in which case the vessel must be cooled by removing a portion of the sand from its upper part. Towards the end of the sublimation the blast must be increased, with the view of bringing the sullimed chloride nearly to its fusing point, for the purpose of causing it to adhere together in a compact cake; but for reasons already assigned, the temperature must not be carried too far, since this would occasion a loss. After the sublimation the fire is withdrawn; and as soon as the sand has sufficiently cooled, the matrasses are taken out and broken in the middle as gently as possible, so as not to detach the crust of salt upon the upper part. Finally, the fragments of glass and discolored parts are removed, and the pure cakes set aside to be ground and packed.

Any subchloride of mercury which may happen to be formed during the sublimation, owing to its not being so volatile as corrosive sublimate, forms a whitish ring on the lower part of the sullimed crust, and thus admits of being removed. Such portions may be added

in the succeeding charge which is being converted into sulphate, and afterwards re-sublimed.

Properties.—Ordinary sublimed chloride of mercury is a white satiny substance having a crystalline appearance, although often no distinct order can be distinguished. If, however, the sublimation be effected at a low heat, and as slowly as possible, crystals appear, having the shape of flattened tetrahedral prisms, Fig.

Fig. 368.

368, with a specific gravity of 5.4. The sublimed salt appears more or less translucent, and when in thin fragments often transparent. In the heat it is very volatile, entering first into fusion before it is disseminated. According to FARADAY, the salt volatilizes at ordinary temperatures, but REIGEL found this not to be the case. Water dissolves it very readily; sixteen parts are required in the cold, but three parts at 212° are sufficient to dissolve one part of it, and the liquid reacts acid to test-paper. A hot, concentrated, aqueous solution of mercurial chloride deposits crystals on cooling, which slightly differ in appearance from those obtained by sublimation: they are anhydrous. Alcohol and ether also take it up very freely; seven parts of cold alcohol dissolve three of corrosive sublimate, but the same quantity at a boiling temperature takes up six parts of the salt. When sulphuric ether is added to a solution of corrosive sublimate in water, the mobile liquid abstracts the salt, and an ethereal solution of chloride of mercury floats on the water, which is more or less reduced of its saline constituent. Acids aid in the solution of this body in water, without, however, causing any decomposition or alteration of it. Hydrochloric acid converts it, however, into a hydrochloride of chloride of mercury; sulphide of hydrogen in excess gives rise to a black protosulphide of mercury, but if this agent be sparingly added, a compound of sulphide and chloride of mercury is produced. Potassa in excess throws down the protoxide, but if the solution be not saturated with the alkali, a white oxychloride separates. Ammonia gives rise, also, to an amidochloride of mercury, which an excess of ammonia dissolves. A solution of iodide of potassium throws down a scarlet precipitate of iodide of mercury. Protochloride of tin causes at first a reduction to the subchloride of mercury, which precipitates; but this also becomes reduced to the metallic state, hydrochloric acid being set free in the liquid. By exposure to sunlight an aqueous solution of the salt suffers decomposition into calomel, hydrochloric acid, and oxygen, thus:—

It is likewise decomposed by various substances, metallic, non-metallic, and organic; the latter usually converting it to the state of subchloride. It forms insoluble, or at least but very partially soluble precipitates with albumen and fibrin.

The centesimal composition of protochloride of mercury corresponds with the chemical formula Hg Cl , as shown in the annexed:—

	At Weight.	Centesimally. Theory.
1 Eq. of mercury,.....	100	73.86
1 Eq. of chloride,.....	35.5	26.14
1 Eq. of chloride of mercury, ..	135.5	100.00

Chlorine gas,	1	2.4543
Vapour of chloride of mercury,...	1	6.3843

On all animals the effects of chloride of mercury are, as its technical name implies, those of a corrosive poison, and by its external application even, it has proved fatal to man. When swallowed in any quantity, the symptoms come on almost immediately. Indeed, the rapidity of their appearance and the strong metallic taste which is experienced, are among the phenomena which strongly distinguish cases of poisoning by this agent from those occasioned by arsenic. According to WRIGHT, the best antidote against its poisonous action is the white of egg suspended in water and milk—one egg is said to be required for every *four grains* of the poison; hydrated sesquioxide of iron has also been recommended, and likewise, on account of the gluten it contains, wheat-flour and water. In this country it is little employed internally for allaying human maladies; and even its external application is not free from danger. In veterinary practice, however, it is frequently used, especially in the form of ointment or wash.

The salt has been extensively employed for the preservation of subjects of natural history, and likewise for preserving wood against the dry rot.

Compound Chlorides of Mercury.—Corrosive sublimate is capable of entering into combination with hydrochloric acid and most of the metallic chlorides, forming well-defined crystallizable salts. Thus, with hydrochloric acid it produces a compound, expressed by Hg Cl , HCl or Hg Cl_2 , HO ; with chloride of potassium, Hg Cl , KCl , 2 HO , 2 Hg Cl , KCl , 4 HO , and 4 Hg Cl , KCl , 8 HO_2 . Soda, lithia, baryta, strontia, calcia, and magnesia salts react in the same way, as also the chlorides of manganese, iron, nickel, and cobalt, all of which produce with the mercurial salt well-defined crystalline compounds.

The same compound, when cautiously treated with a dilute solution of a fixed caustic alkali, or with one of the carbonates of the alkalies, gives rise to a compound of chloride and oxide of mercury, having the composition Hg Cl , 3 Hg O —a chloride of the alkali in the first case, and a bicarbonate in the second instance, being formed. All these, however, though interesting to the theoretical chemist, are as yet of no practical utility, and therefore will not be discussed here at greater length. At the same time there is one combination which arises from the addition of ammonia to a solution of chloride of mercury, that has many valuable properties in medicine, and on that account merits a short description, namely:—

Amido-Chloride of Mercury—White Precipitate.—

This compound is obtained by adding to a solution of two equivalents of the chloride of mercury—271 parts—in a large quantity of water, a solution of ammonia

as long as a precipitate is formed, collecting the separated substance, washing with cold water, and drying.

For a long time this body was thought to be identical with calomel, till RAMMELSBURG showed it to be different, and KANE demonstrated its true composition, in his researches on the *Amides*. The reactions in its formation may be expressed thus:—

That is to say, one equivalent of the volatile alkali suffers decomposition into amidogen— NH_2 —water and hydrogen; the amidogen takes an equivalent of the mercury from the corrosive sublimate and sets free chlorine, which seizes on the ammonium of the second equivalent of the alkali, and forms chloride of ammonium, thus liberating its oxygen to the hydrogen set free in the first change.

Amido-chloride of mercury forms a snow-white mass, without odor, but possessing a nauseous metallic taste. It requires for solution about six hundred parts of water, but the mineral acids readily dissolve it. When heated it volatilizes without fusing, but WITTSTEIN states that the same compound, when obtained from chloride of mercury, chloride of ammonium, and a fixed alkaline carbonate, melts in the heat before dissipation. In either case the compound is completely broken up into corrosive sublimate, ammoniacal gas, and nitrogen, as shown by the equation:—

When the precipitate is boiled in water, chloride of ammonium is produced, and a heavy yellow powder composed of two equivalents of protoxide of mercury, one of protochloride, and one of amide of mercury falls. Potassa likewise changes it into oxide and chloride of the metal, ammonia being evolved. Caustic ammonia has no apparent action, and hence this alkali serves to distinguish it from calomel, which is turned grey or blackish by it. Its composition is given:—

This compound, in a physiological point of view, has been but imperfectly studied. It is, however, regarded as an energetic poison, in this exhibiting a similarity with corrosive sublimate. It is never administered internally, but may be used externally in the form of an ointment, and is efficacious in various skin diseases. In cases of poisoning with this substance, albuminous antidotes, such as are given to reduce the action of corrosive sublimate, serve best. It is said that white precipitate is much adulterated with sulphate of lime,

carbonate of lime, and carbonate of lead. The extent of the adulteration may readily be found by heating a weighed quantity, and weighing the residue should any be left.

Iodide of Mercury.—Iodine and mercury are capable of entering into several states of combination; and some of the compounds so formed are capable of constituting binary salts with the alkaline iodides. Thus, there is the green iodide of mercury, $\text{Hg}_2 \text{ I}$; the yellow iodide, $\text{Hg}_2 \text{ I}_2 = \text{Hg}_2 \text{ I, Hg I}$, and the red iodide, Hg I . The latter compound produces, with iodide of potassium, a mono- bi- and tri-iodargyrate of potassium, the composition of which respectively is Hg I, KI ; 2 Hg I, KI , 6 H O , and 3 Hg I, KI . There are formed similar compounds from the iodide of mercury and the soluble chlorides, but as objects of manufacture, they are of no interest. Respecting the manufacture of the scarlet iodide of mercury, the reader will find particulars under iodine at page 398.

FULMINATE OF MERCURY.—*Fulminating Mercury*; *Mercur fulminante*, French; *knallquecksilber*, German.—This very explosive compound was first described by HOWARD in the Philosophical Transactions for 1800. BRANDE gives the following method for its preparation:—One hundred grains of mercury are treated with an ounce and a half by measure of nitric acid, aided by heat in a porcelain basin, till the whole is dissolved. As soon as the liquid is cold, two ounces by measure of alcohol, specific gravity .85, are added, and a gentle heat applied. Brisk action takes place, ethereal vapors being copiously evolved, and a yellow-grey precipitate deposited, which is the compound in question. If the effervescence be too brisk, the vessel should be withdrawn from the heat, and its contents cooled by the addition of more alcohol. As soon as the precipitate has formed, it is to be well washed by decantation and filtration, only a small quantity of distilled water being used in the latter process. The temperature at which the compound is dried should not exceed 100° , and only small quantities ought to be operated upon at a time to guard against an explosion. One hundred and twenty grains of the fulminate are obtained from the above quantity of mercury when the operations are successfully conducted. It happens that on the addition of the alcohol, a portion of the mercuric salt is reduced to the state of metal, but this can be separated from the yellowish salt after the spirit is decanted by treating with boiling water, in which the fulminate is soluble; and by filtering off the liquor and setting it aside to cool, the salt separates in silky acicular crystals. When it is required to prepare it in large quantities, the course followed is to dissolve one part of mercury in twelve of nitric acid of 1.36 specific gravity, and to add eleven parts of alcohol, specific gravity .850, when the solution is cold. On slightly heating the vessel, brisk action takes place as above stated, and similar effects are produced. The separated metal is removed from the explosive compound by boiling water, from which the fulminate is deposited on cooling in silky crystals. CREMASCOLI directs, as the safest method, to treat half an ounce of the metal with six ounces of nitric acid of 1.30 in a flask, which should be held in boiling water for a minute or so, and as

soon as solution takes place, and the temperature is reduced to 55° , to pour in four ounces of alcohol of $\cdot 833$ specific gravity, and again to immerse the flask in boiling water for two or three minutes, till dense white vapors begin to fill the upper part of the vessel, at which period it should be removed from the heat. The reaction is said to be very moderate in this instance, and the whole of the fulminate falls down in the course of a few hours, when it may be purified by decantation and washing.

Fulminate of mercury forms an extremely dangerous substance to operate upon, owing to the readiness with which it explodes, the violence of which has repeatedly been the cause of serious injury, and even of loss of life. It detonates strongly when struck with a hard body; but sometimes trifling friction may serve to produce this effect, even when in a moist state. Heated to 300° it explodes, and at the same time evolves a bright flame; the electric spark, and contact with strong nitric and sulphuric acids, also induce its decomposition, which is invariably accompanied with explosion. The products resulting from it, when detonated, are carbonic acid, nitrogen, and vapor of mercury. Its chemical formula is expressed by 2HgO , $\text{C}_4 \text{N}_2 \text{O}_2$, or 2HgO , $\text{Cy}_2 \text{O}_2$, that is, two equivalents of protoxide of mercury and one of fulminic acid.

Fulminating mercury has been much used since its discovery for the manufacture of percussion caps for guns, and latterly has been employed in the construction of destructive machines, such as grenades and the like. HOWARD endeavoured to substitute it for gunpowder, but was unsuccessful, owing to the nature of its explosion, which is such as to destroy the gun by its suddenness and force without expelling the shot. When used for priming percussion caps it may be moistened with a little resinous tincture, and dropped into the little capsule, but the universal practice is to mix it with about six per cent. of nitrate of potassa and water, sufficient to reduce the whole to a thin paste. A small quantity of this is dropped into each cap, and carefully dried at a low heat.

Analysis of Mercurial Matters.—Already a short description of the method of analysis pursued in determining the richness of mercurial ores has been given, and although the system of analysis to which reference will now be made is analogous to that described, still, since it is more applicable to mercurial compounds in general, it deserves a short space here. It is known as MILLON'S method, and is conducted as follows:—

A hard German glass tube, such as is generally employed in organic analysis, is taken and drawn out in the form represented by *a*, *b*, *e*, in Fig. 369.

The part *a* is intended for the retention of the reduced mercury, and the rest, from *b* to *e*, for the reduction of the ore or salt of mercury. A plug of asbestos is introduced into the end, *b*, and then fragments of quicklime as far as *d*; the compound to be analysed, in quantities varying from fifteen to twenty grains, is then carefully put in, and fills from *c* to *d*, and fragments of quicklime are made to occupy the rest of the tube to *e*. When nitric acid exists in the compound to be analysed, copper turnings are substituted for the quicklime in the part *b d*. The extremity, *e*, is connected by perforated

corks, quill tubes, and flexible connectors, with the apparatus, *g*, for generating a current of pure dry hydrogen gas. The charged tube being placed in the combustion furnace, *f*, and connected with the apparatus, *g*, and filled with gas, ignited charcoal is placed

Fig. 369.

round the part from *b* to *c*, and as soon as this is red-hot the remainder is gradually heated to redness to the end, the current of gas being still maintained. During this operation the mercury is disengaged, and collects in the part, *a*, the water which is generated or contained in the substance being carried off by the current of hydrogen. When the operation is over, the narrow neck near *b* is cut off, and the part containing the reduced metal weighed; after this, the metal is taken out, and any portions remaining dissolved with nitric acid, then washed with distilled water, dried and reweighed. The difference of the two results will be the weight of metal in the sample operated upon.

Provided no easily reduced metal be contained in the substance to be assayed, a quicker method may be resorted to. It consists in adding to the solution of the compound, as free from nitric acid as possible, protochloride of tin, acidulated with hydrochloric acid, and collecting the precipitated mercury on a weighed filter, washing and drying under the exhausted receiver, over sulphuric acid, and weighing.

To Dr. DALZELL, of Edinburgh, the Editor feels indebted for much of the valuable matter contained in this article, and kindly supplied gratuitously and unsolicited.

NICKEL.—English, French, and German.—It was CRONSTEDT who, in 1751, showed that nickel was a distinct body. MILLER remarks that it always occurs in nature associated with iron, both as a constituent of meteoric iron, and in the ores of that metal, which present a composition analogous to those of cobalt. Nickel may be obtained pure upon a small scale by dissolving the roasted ore in aqua regia, evaporating to expel the excess of acid, redissolving in water, and transmitting through the menstruum a current of sulphide of hydrogen. The filtrate is boiled with nitric acid, to sesquioxidize the iron; the solution is precipitated by an excess of ammonia, filtered from the ferruginous oxide, and to the blue liquid potassa is added until the azure tint entirely disappears. A pale-green precipitate, consisting of hydrated oxide of nickel and potassa, is thus obtained, which must be well washed with hot water to remove the alkali, and then reduced by ignition in a current of hydrogen gas. If heated for an hour by means of a blacksmith's forge, in a crucible lined with charcoal, a well-fused button of carbide of nickel is produced; a globule of the pure metal may,

however, be procured by heating the oxalate of nickel intensely in a crucible with a luted cover, without any other reducing agent than the carbonic oxide furnished by the decomposition of the vegetal acid.

Pure nickel is a brilliant, silver white, ductile metal, little more fusible than iron. At ordinary temperatures it is susceptible of magnetism, but it loses this property almost entirely if heated to a point exceeding 630°, though it recovers its magnetic power on cooling. Nickel becomes oxidized by exposure to a current of air at an elevated heat. The metal is easily attacked by nitric acid and aqua regia, and is dissolved slowly, with evolution of hydrogen, in sulphuric or in hydrochloric acid. Its specific gravity is 8·82; its symbol Ni; and its equivalent 29·5.

SOURCES.—Native nickel occurs at Westerwald in the Erzgebirge, in Bohemia, combined with arsenic, under the significant name of *kupfernickel*; with cobalt, iron, and copper, as *arsenic-nickel*, in the Hartz; at Riechelsdorf in Hesse, as an oxide, in *nickelschwartze*; as a sulphide in *haarkies*; as a sulphide and arseniate of nickel in *nickelglanz*; and with sulphur and antimony in *nickelspeisglanz*, at Siegen, and near Freussberg, in the principality of Nassau. Nickel is always present in meteoric stones. Kupfernickel occurs in numerous external shapes; as uniform, globular, botryoidal, arborescent, massive, and disseminated; fracture, coarse or fine grey; in silver and cobalt veins, in gneiss, sienite, mica-slate, kupfer-schiefer, accompanied by speiss cobalt, native silver, quartz, *et cetera*. It is found in Westphalia near Ospe, in Hesse at Riechelsdorf, and Biber in Baden; in the Saxon Erzgebirge, near Schneeberg and Freiberg; in Bohemia, at Joachimsthal; in Thuringia, at Saalfeld; in Steyermark, near Schladming; in Hungary, France, and England.—*Ure*.

Subjoined are the analyses and characteristic properties of a few of the more important of these minerals:—

Kupfernickel.—The composition of this mineral, as stated by STROMEYER and PFAFF, is as follows:—

Centesimally.		Riechelsdorf.	
Nickel,	44·20	48·90
Arsenic,	54·70	48·70
Iron,	0·33	0·44
Lead,	0·32	0·96
Sulphur,	0·45	0·90
Loss,	—	0·10
	100·00		100·00

It is of a copper or yellowish-red hue, but acquires a grey or blackish tarnish by exposure. The specific gravity is 6·6—7·6. It occurs reticulated, dendritic, and botryoidal, but more commonly massive; never crystallized; streak, pale brownish-black. The fracture is imperfectly conchoidal, or fine-grained and uneven, with a glistening or shining metallic lustre; it yields to the knife with difficulty, and is brittle. Before the blowpipe it gives out an arsenical vapor, and then fuses, though not very easily, into a white metallic globule. After roasting, it usually tinges a bead of borax blue, indicating the presence of a certain quantity of cobalt. In nitric acid it assumes a green coating, and in aqua regia is dissolved.

Haarkies—Sulphide of Nickel.—The following is ARFEDSON'S analysis:—

Centesimally.	
Nickel,	64·76
Sulphur,	35·24
	100·00

With traces of cobalt and arsenic. Its specific gravity is 6·45.

It occurs in capillary and sometimes diverging filaments of a yellowish color, inclining to steel-grey. Primary form the cube; flexible; opaque, with a metallic lustre; not magnetic. Before the blowpipe on charcoal, with a good heat, it fuses into a globule which is metallic, malleable, and magnetic, and consists wholly of nickel; but in the open tube it exhales the smell of sulphurous acid. With nitric acid it forms a greenish solution.

Nickelspeisglanz.—This mineral is generally a combination of nickel, sulphur, and antimony, in the following proportions:—

Centesimally.	
Nickel,	27·36
Sulphur,	16·98
Antimony,	55·66
	100·00

Its specific gravity is 6·45—6·5, and its primary form a cube. It occurs in masses, which have a granular composition, and possess a steel-grey or silver-white color; lustre, metallic; cleavage, perfect parallel to the faces of the cube; brittle. Before the blowpipe it is partly volatilized, disengaging vapors of antimony and sometimes of arsenic, and ultimately melts into a metallic globule, which communicates a blue tinge to glass of borax. It is acted upon by nitric acid, forming an immediate precipitate, and imparting to the solution a greenish tinge.

Meteoric Stones.—A natural alloy of nickel and iron, forms a principal metallic ingredient in most *aérolites*, or *meteoric stones*. Though nothing is really known of the source or origin of these bodies, remarks BRANDE, it has been ascertained upon satisfactory evidence, that they are not of terrestrial formation; and, consequently, their visits to the surface of this planet have awakened much speculation, and some experimental research. The first tolerably accurate narration of the fall of a meteoric stone relates to that of Ensisheim, near Basle, upon the Rhine, which fell in 1492, and weighed two hundred and fifty-five pounds. The account which is deposited in the church, runs thus:—Anno Domini 1492, Wednesday, November seventh, there was a loud clap of thunder, and a child saw a stone fall from heaven; it stuck into a field of wheat and did no harm, but made a hole there. The noise it made was heard at Lucerne, Villing, and other places. On the Monday, King MAXIMILIAN ordered the stone to be brought to the castle, and having conversed about it with the noblemen, said the people of Ensisheim should hang it up in their church, and his Royal Excellency strictly forbade anybody to take anything from it. His Excellency, however, took two pieces himself, and sent another to Duke SIGISMUND of Austria.

In 1627, November twenty-seventh, GASSENDI saw a burning stone fall on Mount Vaisir, in Provence; he found it to weigh fifty-nine pounds. In 1672 a stone fell near Verona weighing three hundred pounds. LUCAS, when in Larissa in 1706, describes the falling of a stone with a loud hissing noise, and smelling of sulphur. In September, 1753, DE SALANDE witnessed this phenomenon near Pont de Vesle. In 1768 no less than three stones fell in different parts of France. In 1790 there was a shower of stones near Agen, witnessed by DARCET and several other persons. On the thirteenth December, 1795, a stone fell near Major TOPHAM's house in Yorkshire; it was seen by a ploughman and two other persons, who immediately dug it out of the hole it had buried itself in; it weighed fifty-six pounds.

Various other and equally satisfactory accounts of the same kind are narrated. All concur in describing a luminous meteor, moving through the air in a more or less oblique direction, attended by a hissing noise, and the fall of stony or semimetallic masses in a heated state. There exists, however, evidence of another kind, proving the peculiar origin of these bodies. It is, that although they have fallen in very different countries and at distant periods, when submitted to chemical analysis they agree in component parts; the metallic particles being composed chiefly of iron and nickel, with magnesia and silica.

Large masses of native iron have been found in different parts of the world, of the history and origin of which nothing very accurate is known. Such are the great block of iron formerly at Elbogen in Bohemia; the large mass discovered by PALLAS, weighing sixteen hundred pounds, near Krasnojark in Siberia; that found by GOLDBERRY in the great desert of Zara in Africa; probably, also, that mentioned by BARROW, on the banks of the great Fish-river in Southern Africa; and those noticed by CELIS, HUMBOLDT, and others, in America, of enormous magnitude, some exceeding thirty tons in weight. That these should be of the same source as the other meteoric stones, seems at first incredible; but when they are submitted to analysis,

and the iron they contain found alloyed with nickel, it no longer seems credulous to regard them as of meteoric origin. Nothing of the kind is found in the earth. Two blocks of such iron were, in fact, observed to fall from a meteor at Hradschina, near Agram, in Croatia, in 1751.

To account for these remarkable visitations of metallic and lapideous bodies, a variety of hypotheses have been suggested. Are they merely earthy matter, fused by lightning? Are they the offspring of any terrestrial volcano? These were once favorite notions; there is no instance recorded in which similar bodies have in that way been produced, nor do the lavas of known volcanoes in the least resemble them; to say nothing of the inexplicable projectile force that would be here wanted.—*Brande*.

The notion that these bodies come from volcanoes in the moon is no longer received. The most plausible hypothesis is that of HUMBOLDT, who supposes that meteoric stones are, in fact, small planets continually wandering in myriads through the celestial spaces, but which occasionally come within the earth's attraction, and fall to the ground.

In meteoric iron the proportion of nickel varies considerably. In a specimen from the Arctic region, BRANDE found 3·2 per cent. In that from Siberia, CHILDREN obtained nearly ten per cent. The analysis may be performed by solution in nitro-hydrochloric acid; the iron is thrown down by excess of ammonia in the state of sesquioxide; it is separated by filtration, washed, and dried; and on evaporating the filtrate, and heating its dry residue red-hot, the oxide of nickel is obtained, which should be redissolved in nitric acid, and precipitated by pure potassa, the mixture being boiled for a few seconds; or the nitro-hydrochloric solution may be precipitated by excess of ammonia, and filtered: the sesquioxide of iron remains upon the filter, and the filtrate is an ammoniacal solution of nickel, from which the metal may be precipitated by ferrocyanide of potassium. The following are some further analyses of meteoric iron:—

	Klaproth.		M. de Rivers and Boussingault.			
	Sclavonia.	Siberia.	From the Andes.			
Iron,	96·5	98·5	91·51	91·23	91·76	90·76
Nickel,	3·5	1·5	8·49	8·21	6·36	7·87
Loss,	—	—	—	0·56	1·88	1·37
	100·0	100·0	100·00	100·00	100·00	100·00

MANUFACTURE.—The nickel of commerce is chiefly obtained from kupfernickel, nickeliferous pyrites, and from the speiss obtained as a secondary product in the treatment of nickeliferous ores of cobalt. The most productive mines of this metal are those of Saxony, Germany, and Norway. The preparation of pure nickel from speiss is conducted in accordance with a method first proposed by WÖHLER. The powdered speiss is roasted, first alone, and afterwards with the addition of powdered charcoal, to effect the separation of its arsenic. The residue obtained by this process is at present mixed with three parts of sulphur, and one part of carbonate of potassa, and then fused in a large earthen

crucible. This product is nowedulcorated with warm water, by which the arsenic and sulphur associated with potassium are dissolved, while the nickel, in the form of sulphide, remains at the bottom of the vessel in which the operation has been conducted. When, as sometimes happens, from the employment of too high a temperature at the commencement of the roasting, the whole of its arsenic has not been expelled, the operation must be repeated on the residual sulphide thus obtained. As soon as entirely freed from arsenic, the sulphides are well washed with warm water, and then dissolved in sulphuric, to which a small quantity of nitric acid has been added; the precipitation of the

lead, copper, and bismuth, which may be present, is determined by a current of sulphide of hydrogen gas, and the metals which still remain in solution are afterwards precipitated by an alkaline carbonate. This deposit, after being well washed, is then treated with an excess of oxalic acid, which forms an insoluble oxalate of iron, and leaves behind an insoluble oxalate of the oxides of cobalt and nickel. These are then dissolved in ammonia, and treated as already described. The oxalate of nickel deposited from this solution is, after being carefully washed to remove any traces of the ammoniacal liquor, ignited in a close crucible, having an aperture in the lid for the escape of the evolved gases.

As the metal itself is now extensively used in alloys, of which German silver is one of the most important, great pains have been taken to procure it in a state of comparative purity, and several processes have been proposed. According to LOUYER, the process by which nickel is extracted from speiss at Birmingham, on the large scale, is as follows:—The speiss is first fused with chalk and fluorspar, the metallic mass obtained is reduced to powder, and roasted for twelve hours to expel the arsenic; the residue is then dissolved in hydrochloric acid; the solution is diluted, and the iron sesquioxidized by the cautious addition of chloroxide of calcium—bleaching powder—milk of lime is then carefully added so long as sesquioxide of iron falls, which carries down with it the last portions of arsenic. This precipitate is well washed, and the liquid, which contains all the cobalt and nickel, is treated with a current of sulphide of hydrogen; the sulphides of copper, bismuth, and lead are thus precipitated, and are thoroughly washed. The whole of the nickel and cobalt still remain in the liquid, which is again treated with chloroxide of calcium: the cobalt is thus thrown down as sesquioxide; after which the total quantity of the nickel is separated from the solution in the form of hydrated oxide, by adding milk of lime as long as any precipitate is produced.

For the separation of nickel and cobalt, the method recommended by LIEBIG is the best. The cobalt and nickel having been freed from all other substances except salts of potassa or soda, are precipitated in the form of hydrated oxides, which, after partial washing from the adhering alkaline salts, are mixed with caustic potassa and a decided excess of hydrocyanic acid; the mixture is then boiled for ten minutes in order to expel the greater part of the excess of hydrocyanic acid, and to convert the oxides into double cyanides of cobalt and nickel. A cobaltcyanide of potassium— $K_3 Co_2 Cy_6$ —is produced at the same time. The formation of the cobaltcyanide may be traced as follows:—cyanide of cobalt is first formed, $H Cy + Co O = Co Cy + HO$, and this cyanide of cobalt, by boiling with an excess of cyanide of potassium and hydrocyanic acid, yields cobaltcyanide of potassium and free hydrogen, $2 Co Cy + 3 K Cy + H Cy = K_3 Co_2 Cy_6 + H$. The double cyanide of nickel and potassium is very simply formed, as with nickel no compound corresponding to the cobaltcyanide is obtained; $2 K Cy + Ni O = K Cy + Ni Cy + HO$. If the solution be now boiled with very-finely levigated

oxide of mercury, the nickel salt is decomposed, hydrated oxide of nickel is precipitated, and cyanide of mercury is produced:—

The cobaltcyanide of potassium is not decomposed by the oxide of mercury, but remains in solution, and may be filtered from the oxide of nickel, which requires to be carefully ignited in a platinum crucible till it ceases to lose weight. The cobalt may then be precipitated from the filtrate as a white subcobaltcyanide of mercury, by the addition of solution of subnitrate of mercury; the precipitate is collected, dried, and ignited, when pure oxide of cobalt is left, which may be reduced to the metallic state in a current of hydrogen.

The solution of the oxides, which must be free from nitric acid, is, after previous neutralization of the free acid which may be present, by ammonia, precipitated with sulphide of ammonium, and highly dilute hydrochloric acid, according to ROSÉ, or acetic acid—WACKENRODER—is then added. This serves to dissolve the sulphide of manganese and the sulphide of iron, whilst the sulphide of cobalt and the sulphide of nickel remain undissolved, though the latter less completely. The sulphides of the metals are re-precipitated from the filtrate by the addition of ammonia and sulphide of ammonium, and the precipitate is treated once more with dilute hydrochloric acid. The results are nearly accurate. The cobalt and nickel can be determined by LIEBIG's method, as given above.

Nickel is separated from manganese and zinc by the annexed process of EBELMEN. Put the weighed mixture of the oxides in a small platinum vessel, insert this into a tube, heat the mixture to dull redness, conducting all the time sulphide of hydrogen gas over it. Let the sulphides formed cool in the gaseous stream, and then digest them for several hours with cold dilute hydrochloric acid, which dissolves only the sulphides of manganese and zinc. The sulphides of cobalt and nickel are left behind in a perfectly pure state, and may be separated, if desired, as above, by dissolving in aqua regia, *et cetera*. The reader will find much valuable information with respect to nickel under COBALT, Vol. I., page 492.

ALLOYS OF NICKEL.—FARADAY states that meteoric iron has been imitated by fusing iron with nickel. The alloy of ninety iron with ten nickel is of a whitish-yellow cast, and not so malleable as pure iron. The alloy with three per cent. of nickel is perfectly malleable and whiter than iron. These alloys are less disposed to rust than pure iron, but nickel alloyed with steel increases the tendency to rust.

BRANDE remarks that nothing is known of the alloys of nickel with *potassium, sodium, manganese, zinc, or tin*. With *copper* it forms a hard white alloy; the *white copper* of the Chinese, or *Pakfong*, consists, according to the analysis of Dr. FYFE, of 40.4 parts of copper, 31.6 of nickel, 25.4 of zinc, and 2.6 of iron.

German Silver.—A similar alloy is often used as a

substitute for silver, or for plated articles, under the name of *German silver*. It should consist of one part of nickel, one of zinc, and two of copper; or, when intended for rolling, of twenty-five parts of nickel, twenty of zinc, and sixty of copper; to which, if for casting, three of lead may be added. The following details respecting the alloys of nickel, are from a pamphlet on the subject by Messrs. TOPPING. The metals referred to should be as pure as possible. *Common German Silver*.—Copper 8, nickel 2, zinc 3.5. This is the commonest that can be made with any regard to the quality of the article produced, and may be used for ware for ordinary purposes. If the quantity of the nickel be reduced much below this, the alloy will be little better than pale brass, and tarnish rapidly. *Good German Silver*.—Copper 8 nickel 3, zinc 3.5. This is a very beautiful compound. It has the appearance of silver a little below standard; by some persons it is even preferred to the more expensive compounds. *Electrum*.—Copper 8, nickel, 4, zinc 3.5. This is the compound first introduced by Messrs. TOPPING, and they still prefer it to any of the others. It has a shade of blue like very highly-polished silver: it tarnishes less easily than silver.—Copper 8, nickel 6, zinc 3.5. This is the richest in nickel that can be made, without injuring the mechanical properties of the metal. It is a very beautiful compound, but requires a higher heat for fusion than the preceding, and will be found rather more difficult to work. *Tutenag*.—Copper 8, nickel 3, zinc 6.5. The proportions were originally obtained by analyzing a piece of Chinese tutenag of the best ordinary quality; but some rare specimens of Chinese tutenag, equal to electrum, have been seen. This alloy is very fusible, but very hard, and not easily rolled: it is best adapted for casting. A variety of articles are now plated with nickel by electrolytic precipitation from a solution of sulphate of nickel, the process being in all respects similar to that in which copper is used. SMEE recommends chloride of nickel as the solution, when electroplating with this metal, with a nickel positive pole and single battery; the nickel thus deposited, he says, is very brilliant, but rather brittle.

CHEMICAL COMBINATIONS.—Nickel forms two oxides: a protoxide, NiO —and a sesquioxide, Ni_2O_3 .

Protoxide of Nickel may be procured in the anhydrous form by igniting the carbonate in a covered crucible, when it is left of an olive-green color. It may be precipitated from its salts by potassa, as a bulky light-green hydrate— NiO, HO —and may be obtained crystallized by boiling carbonate of nickel in ammonia. Oxide of nickel forms insoluble compounds with potassa or soda, which, however, may be decomposed with frequent affusions with boiling water. Baryta, strontia, and several other bases, also yield with it insoluble compounds; ammonia dissolves it, forming a deep-blue solution. When fused with borax, the oxide tinges the glass of a hyacinth yellow, which becomes less intense on cooling.

Sesquioxide— Ni_2O_3 —is a black powder, which may be procured by treating the hydrated protoxide with a solution of chloroxide of sodium. It is singular that it does not combine with acids, but gives off a portion of its oxygen by ignition, or by heating with

nitric or sulphuric acids, which form with it salts of the *protoxide*.

Sulphide of Nickel— NiS —occurs native in greyish or yellowish capillary crystals; it may be produced artificially by fusion, and can be obtained as a black hydrate, when a salt of nickel is precipitated by sulphide of ammonium.

Chloride of Nickel— $\text{NiCl} + 9\text{HO}$ —is formed by dissolving the oxide in hydrochloric acid.

Sulphate of Nickel— $\text{NiO}, \text{SO}_3 + 6\text{HO}$ —which results from the action of sulphuric acid on the metal, or its oxide, crystallizes in green rhombic prisms; these, when exposed to light, are converted, without loss of water, into small regular octohedra, aggregated together in the form of the original crystal, which becomes opaque.

CHARACTERS OF THE SALTS OF NICKEL.—The salts of this metal are of a delicate green hue, both when in the solid state and in solution. They have a sweetish astringent metallic taste.

Before the blowpipe, salts of nickel give, in the oxidating flame, with biborate of soda, a reddish-yellow glass, which becomes much paler as it cools. In the reducing flame, greyish particles of reduced nickel are disseminated through the bead.

In solution *sulphide of hydrogen* gives no precipitate, if the liquid be acidulated with sulphuric acid. *Sulphide of ammonium* gives a black sulphide. *Ammonia* gives a pale-green deposit, soluble in excess of ammonia, forming a bright blue solution. *Potassa* and *soda* throw down a pale-green bulky hydrated oxide of nickel. The *carbonates of the alkalies* give a pale apple-green precipitate of basic carbonate of nickel, which is readily soluble in carbonate of ammonia. *Ferrocyanide of potassium* affords a greenish white, and *ferridcyanide of potassium* a yellowish-green precipitate.

ANALYSIS.—Protoxide of nickel is always weighed as such. Mix the acid solution of the oxide in a beaker glass with pure potassa, or soda in excess, heat for some time to near boiling, filter, wash the precipitate thoroughly with hot water, dry, and ignite. The presence of ammoniacal salts, or of free ammonia, does not interfere with the precipitation. This method, if carefully executed, gives exceedingly accurate results, which the Editor has often confirmed.

USES.—The nickel obtained in this country, is chiefly employed for the manufacture of Argentane or German silver, which, as stated above, is an alloy of this metal with zinc and copper. Nickel likewise forms one of the constituents of the tutenag of China, and the *Pakfong* of the East Indies. Being exclusively used as an alloy, the nickel of commerce comes into the market in the form of finely-divided grains, or granulations, of the size of small beans. The best German silver consists of eight parts of copper, three of nickel, and three and a half parts of zinc; but an inferior and more common variety is sometimes manufactured from eight parts of copper, two of nickel, and four of zinc. From its magnetic property, a patent has been taken to substitute nickel for the magnetised steel needles employed in COOKE and WHEATSTONE's Electric Telegraph; but it has not been practically applied to this purpose.

NITRIC ACID.—*Acide nitrique*, French; *Salpetersäure*, German; *Acidum nitricum*, Latin.—An interesting paper appeared some time ago, by Mr. THORNTON J. HERAPATH, intended to show that this acid was known to the ancient Egyptians. In his *brochure* Mr. HERAPATH gave a short account of some experiments he had made on certain hieroglyphical marks or letters that had been discovered on the wrappers of a mummy which was unrolled by Mr. NASH at the Bristol Microscopical Society, and, as the result of these, he stated his belief that the ancient Egyptians were acquainted with a marking fluid containing nitrate of silver for its basis, and were also familiar with the use of nitric acid. A short time afterwards, Mr. DENHAM SMITH, in replying to this paper, took exception to these views; and whilst admitting the interesting nature of the discovery that had been made of an argentine solution having been employed some three thousand years ago, as *marking ink*, totally dissented from the conclusions that had been founded on it, inasmuch, he said, as there was no evidence to prove that the Egyptians were even versed in the art of distillation. He also hazarded the opinion, unsupported, however, by direct evidence, that the marking fluid in question was prepared by dissolving either the chloride or oxide of silver in an ammoniacal solution, and, consequently, without the intervention of any acid whatever. As the question in dispute is one of great interest, in a scientific point of view, Mr. HERAPATH pursued the subject, and submitted the marks to a fresh examination. After making several preliminary experiments, he found that no results of any value could be obtained by the ordinary modes of analysis, and was therefore compelled, as a last resource, to call in the aid of the microscope.

On examining with this instrument some of the fibres of the bandages that were stained by the argentine ink, he found them to present a very singular appearance. The ends near the corroded parts of the fabric, were stained of a deep brown or black; but for some little distance beyond the blackened portion, the fabric had a pale yellow hue, as if, during the decomposition of the silver salt that had been employed as *marking ink*, the nitrogenous constituents of the tissue had been partially acted upon, and converted into xanthoproteic acid.

Between several of the fibres, and, in many places, adhering to their external surfaces, were found small particles of some organic tissue, which were tinged of a still deeper yellow than the fibres themselves. On subjecting some of the latter to the action of strong liquor ammonia, the yellow portions, particularly the altered intercellular substance, acquired a still darker hue, whilst those, on the contrary, which were stained by the reduced silver, became slightly paler, as if a part of the argentine film was soluble in that menstruum; though it should be observed that no further effect was produced on the stain, even by a lengthened digestion in ammonia. Now, upon making comparative experiments with a piece of the linen wrapper that had been previously marked in the ordinary manner with solution of nitrate of silver, the fibres were found to present an appearance very similar to that above

described; the only difference being that the yellow coloration was not quite so palpable, and more of the silver stain was eradicated by the solution of ammonia; whereas, on the other hand, fibres that had been stained by solutions of chloride and oxide of silver in ammonia, were uniformly colored of a dark-brown or black, and exhibited no remnant of the yellow coloration.

On the whole, the results of Mr. HERAPATH's microscopic examination appear to justify the conclusion that the ancient Egyptians were really familiar with nitric acid and its uses; and actually employed the nitrate of silver as a marking fluid. In what way, however, they prepared the acid, whether by distillation of the nitrate of soda or of nitrate of potassa with sulphuric acid, may for ever remain a mystery.

Liquid or hydrated nitric acid was known in the seventh century to GEBER, who termed it *solutive water*. It is sometimes called *azotic acid*, and in the time of the alchemists, it was known as *aqua fortis*—a name still retained. The nature of its constituents was shown by CAVENDISH in 1785, and their proportions were subsequently determined by DAVY, GAY-LUSSAC, and THOMSON. When nitrogen is mixed with twelve or fourteen times its bulk of hydrogen, and a jet of the gas is allowed to burn in air or in oxygen, water is formed, which has a sour taste and an acid reaction, from the simultaneous formation of a small quantity of nitric acid. In this case, the nitrogen burns by the aid of the heat developed during the combustion of the hydrogen, and the nitric acid combines at once with the water formed, which much increases its chemical stability. It was, indeed, owing to the accidental production of nitric acid in the course of his experiments on the formation of water by the combustion of hydrogen, that CAVENDISH was induced to institute the train of research which resulted in his important discovery.

If two volumes of nitrogen be mixed with five volumes of oxygen in an inverted siphon containing a few drops of an infusion of litmus, each limb plunging into a separate glass of mercury, and a series of electric sparks be passed through the mixture, the two gases will slowly combine, and the litmus will be reddened. The heat of the spark determines combination of the gases just at the spot through which it passes, but the action does not extend further. In like manner, if a number of sparks be passed from the electrical machine, between two metallic points, over moistened litmus paper in air, a red spot will be produced upon the paper, owing to the formation of nitric acid in minute quantity by the combination of oxygen with nitrogen. During stormy weather, and, indeed, whenever a flash of lightning passes through a humid atmosphere, the same compound results in appreciable quantity. Indeed, rain water always contains traces of nitrate of ammonia, which may be detected, if the experiment is made with sufficient attention to accuracy.

Nitric acid also occurs in combination with potassa or soda, in the form of an efflorescence in the soil, especially in tropical climates, as in some parts of India and Peru. The compound formed with soda constitutes the *nitre*, and with potassa, the *saltpetre* of commerce.

Preparation.—It is either from nitrate of potassa or nitrate of soda that this acid is always obtained for chemical purposes. When saltpetre is heated with sulphuric acid, it is decomposed; an alkaline sulphate remains in the retort, whilst the more volatile nitric acid distils over, and may be condensed in the usual manner. In preparing nitric acid on the small scale, equal weights of nitre and concentrated sulphuric acid are placed in a glass retort, and carefully dis-

tilled. The result of the reaction may be traced as follows:—

or, as it may be illustrated more in detail:—

Red vapors appear in the retort during the distillation, arising from partial decomposition of the acid, and a formation of some of the lower oxides of nitrogen. A yellowish corrosive liquid condenses in the receiver, fuming strongly on exposure to the air, and emitting a powerful, irritating odor.

On the large scale, iron retorts, Fig. 370, coated with fire-clay on the inside of the upper part, where they are exposed to the acid vapors, are employed for the distillation, and nitrate of soda is substituted for the potassa salt, being cheaper, and likewise containing considerably more nitric acid.

The cylinders or retorts are arranged in pairs in a furnace, so that each fire heats two cylinders, as shown in the transverse section. They are furnished with a movable lid, *c, d*, at each end. The nitrate is intro-

Fig 370.

duced into the retort, *A*, through the aperture at *c*, which is closed during the distillation, by a stone lid that fits accurately; the sulphuric acid being introduced by a funnel at *e*, after the retort is closed. As soon as the acid is added, the funnel is withdrawn, and the opening closed with a plug. The acid, as it distils over, passes through the pipe, *f*, and is condensed in a series of stoneware bottles, the first of which is seen at *B*. The acid which condenses in the first receiver, is always contaminated with sulphuric acid, and that in the last is rather dilute, as water is placed in it to condense the nitrous fumes.

It is usual upon the large scale to employ a smaller proportion of sulphuric acid than when the distillation is performed in glass vessels, as it is quite possible to effect a complete decomposition of the nitrate by heating it with one-half its weight of sulphuric acid. Under these circumstances, however, a higher temperature is needed to expel the last portions of acid, and a considerable quantity of the nitric acid is thereby decomposed and wasted. The residue in the retort, when the smaller

quantity of sulphuric acid is used, is much less soluble in water, and consequently is much more difficult of removal; in the iron cylinder of the manufacturer, this is of no moment, as the saline mass can easily be detached by the use of iron tools, when the distillation is at an end. The cause of these differences lies in the fact that sulphuric acid forms with potassa two different compounds, one of which contains twice as much acid as the other. When saltpetre and sulphuric acid are mixed in the proportion of two equivalents of each, half the salt only is decomposed, so long as a gentle heat is employed, and the acid sulphate of potassa is formed. The nitric acid, thus liberated, distils over readily. Annexed is represented the form of this reaction:—

yielding

As soon as the first half of the nitric acid has passed over, the temperature begins to rise, and the bisulphate of potassa then reacts on the undecomposed saltpetre; the second half of the nitric acid is liberated, but at the same time is partially decomposed towards the end of the operation, and the whole of the potassa remains in combination with sulphuric acid in the form of the sparingly soluble neutral sulphate. This second stage of the decomposition is exhibited in the subjoined equation, which will be easily understood from the foregoing:—

When, on the other hand, two equivalents of sulphuric acid are used to one of nitrate of potassa, the whole of the potassa is at once converted into the acid sulphate, so that the total quantity of the nitric acid is liberated immediately, and distils readily:—

The result is, therefore, one equivalent of the bisul-

phate of potassa, and one of nitric acid. These changes will perhaps be better understood by the following tabulation :—

Before decomposition.	After decomposition.
202 = 2 Eqs. of saltpetre, 2 (KO, NO ₅)	101 = 1 Eq. saltpetre.
101 = 1 Eq. nitre (KO, NO ₅)	63 { 1 Eq. liquid nitric acid (HO, NO ₅).
54 = 1 Eq. nitric acid (NO ₅)	{ 1 Eq. of bisulphate
47 = 1 Eq. potassa (KO)	{ of potassa (KO

98 = 2 Eqs. of sulphuric acid, 2 (HO, SO ₃)	136
49 = 1 Eq. sulphuric acid (HO, SO ₃)	
49 = 1 Eq. sulphuric acid (HO, SO ₃)	

PROPERTIES.—In the most concentrated state in which it can be obtained by the preceding process, nitric acid is, when pure, a colorless, limpid, fuming, powerfully-corrosive liquid, having a specific gravity of 1.520. It is the highest oxide of nitrogen known to exist, and contains one equivalent of nitrogen with five of oxygen, associated with one equivalent of water—HO, NO₅. One hundred parts contain 85.71 of the anhydrous nitric acid. Exposure to the light of the sun produces its partial decomposition; mere distillation, in fact, has invariably the same effect. At 184° it begins to boil, and congelation occurs about 40° below zero. It very readily parts with a portion of its oxygen to the metals, and to combustible bodies. If it be dropped into hot, finely-powdered charcoal, the charcoal burns vividly; if mixed with a little sulphuric acid and poured into oil of turpentine, the mixture bursts into flame. Nitric acid has a pungent, rather disagreeable smell, is very acid and corrosive, and stains the skin, and organic matter in general, yellow.

It has a strong attraction for water, and becomes hot when mixed with it. Acid of medium strength, mixed with snow, causes it to liquefy instantly, producing intense cold. Nitric acid acts violently upon tin or iron filings, especially if they be previously moistened with a few drops of water: this acid is, indeed, constantly employed by the chemist as an oxidising agent. In order to produce a rapid oxidation of the metals, it is best to dilute the acid until it has a specific gravity between 1.25 and 1.35.

The action of nitric acid upon the metals is instructive, and it is well remarked by MILLER, from whose excellent work the Editor has largely drawn in the present article, that this action may serve to illustrate the manner in which metallic bodies combine with the acids generally. The metals, he observes, will enter into direct combination with many of the simple non-metallic bodies: thus, antimony will unite directly with chlorine, and will even take fire if allowed to fall in fine powder into the gas. Iron will burn in oxygen; and copper turnings, if mixed with powdered sulphur, will combine with the sulphur on the application of heat, emitting a vivid flash of light. But no metal will unite directly with an acid; in order that the combination between them should occur, it is necessary that the metal should be in the form of oxide. This oxidation, may, however, be effected at the same time that the acid is presented to the metal, and the formation of the oxide and its solution may appear to occur simultaneously. Zinc, for example, does not unite as zinc with sulphuric acid: when this metal is placed in dilute sulphuric acid, the oxygen is supplied from the water which is decomposed, oxide of zinc is produced, and is immediately dissolved by the acid, whilst the hydrogen escapes in the gaseous form. When a metal,

such as copper or silver, is dissolved by nitric acid, a preliminary oxidation is equally necessary; but owing to the facility with which nitric acid is deprived of a part of its oxygen, this oxidation is usually effected at the expense of the nitric acid, which is more readily decomposed than water; some of the lower oxides of nitrogen are liberated in the form of ruddy fumes, whilst the compound of the metal with oxygen dissolves in another portion of the acid which has remained intact. The exact nature of the decomposition which the nitric acid experiences varies in different cases. Silver, when allowed to dissolve slowly in the cold in dilute nitric acid, produces nitrous acid—NO₂—which remains in solution: thus, 2 Ag + 3 NO₅ becomes 2 (AgO, NO₅) + NO₂, and the metal dissolves without evolution of gas; and a similar effect is produced by palladium. With metals which, like copper and mercury, have a somewhat stronger affinity for oxygen, binoxide of nitrogen—NO₂—is disengaged in large quantity; for example, 3 Cu + 4 NO₅ = NO₂ + 3 (CuN, NO₅); and if the metal have a still more powerful tendency to combine with oxygen, as is the case with zinc, the protoxide of nitrogen—NO—is, if the acid be dilute, amongst the vapors disengaged: 4 Zn + 5 NO₅ would produce NO + 4 (Zn O, NO₅). Zinc and tin also decompose water as well as nitric acid when dissolved in the acid, eliminating hydrogen, which, as soon as it is evolved, completely deprives a portion of nitric acid of its oxygen, and forms ammonia by entering into combination with the liberated nitrogen; for instance, 8 Zn + 8 HO + 8 NO₅ = 8 (ZnO, NO₅) + 8 H, and NO₅ + 8 H yield 5 HO + NH₃.

When the concentrated acid is exposed to the air it imbibes moisture; and if mixed with water it absorbs a sensible amount of heat, owing to the formation of another hydrate of much greater persistency. This stable hydrate contains four equivalents of water, and one of nitric acid (HO, NO₅ + 3 Aq.); it has a specific gravity of 1.424, and is composed of sixty per cent. of anhydrous acid, and forty of water. This hydrate has a higher boiling point than the protohydrate, and distils at 250° unaltered.

Anhydrous Nitric Acid.—Nitric acid, says MILLER, may be obtained anhydrous by DEVILLE's method, in which state it forms perfectly transparent, brilliant, colorless crystals, derived from the right rhombic prism; they melt at 85°, and boil at 113°; at about this temperature the compound begins to be metamorphosed. Sometimes the crystals, even if kept in sealed tubes, undergo decomposition at the ordinary atmospheric temperature, and the tube bursts with a dangerous explosion from the pressure exerted by the liberated gases. The crystals dissolve rapidly in water, emitting much heat, and producing ordinary nitric acid.

The process consists in passing a uniform current of

perfectly exsiccated chlorine gas very slowly over crystals of well-dried nitrate of silver; the salt is heated to about 200° at first, till the decomposition has commenced, and the temperature is then lowered to about 150° . The operation is one of considerable delicacy, and requires attention to a number of minute precautions, for the details of which the reader is referred to M. DEVILLE's paper. The apparatus required is shown in Fig. 371. A is a vessel of concentrated sulphuric acid; the acid is drawn off from it by the siphon, and allowed to flow into the vessel B, in a very

Fig. 371.

slender stream, which can be regulated by the glass stopcock; B has also been filled with sulphuric acid, and subsequently charged with pure dry chlorine, by means of the bent tube, H. C is a tube filled with dry chloride of calcium; D a tube filled with pumice moistened with sulphuric acid; E a tube filled with nitrate of silver in crystals, immersed in a bath of oil; F the receiver for the anhydrous nitric acid, which is kept cool by a mixture of ice and salt. The tubes E and F are made of one continuous piece of glass, as the acid immediately attacks and destroys cork or caoutchouc joints; a portion of one of the lower oxides of nitrogen is liquefied and collected in the tube in F, and is then separated. The chlorine displaces the nitric acid and oxygen from the nitrate of silver; chloride of silver is formed, and the nitric acid and oxygen escape. By surrounding the receiver, F, with a freezing mixture, the nitric acid is condensed in crystals. The decomposition is of the following simple character:—

The composition of anhydrous nitric acid was determined by DEVILLE, by estimating the quantity of nitrogen which a given weight of the acid furnished after the oxygen had been removed from it by heating it in contact with copper, which rapidly combines with oxygen at a higher temperature. M. DEVILLE found in one of his experiments, that five hundred and forty-seven milligrammes of acid, gave one hundred and sixteen cubic centimetres of nitrogen, at a temperature of 41° , whilst moist, and under a barometric pressure of seven hundred and fifty-seven millimetres. This, when corrected, gives in one hundred parts of the acid by weight, 25.9 of nitrogen; the deficiency, 74.1, is

oxygen; or fourteen parts of nitrogen are united with forty of oxygen.—Miller.

The subjoined is an abridgment of a table, giving the per-centage of anhydrous nitric acid contained in aqueous solutions of various specific gravities, as determined by Dr. URE:—

Specific gravity.	NO ₅ in one hundred parts by weight.	Specific gravity.	NO ₅ in one hundred parts by weight.
1.5000	79.700	1.2887	39.053
1.4940	77.303	1.2705	36.662
1.4850	74.918	1.2523	34.271
1.4760	72.527	1.2341	31.880
1.4670	70.136	1.2148	29.489
1.4570	67.745	1.1958	27.098
1.4460	65.354	1.1770	24.707
1.4346	62.963	1.1587	22.316
1.4228	60.572	1.1403	19.925
1.4107	58.181	1.1227	17.534

1.3056	41.444	1.0053	0.797

Tests for Nitric Acid.—No ready method is known of precipitating nitric acid from its solutions, since all its compounds dissolve more or less freely in water. Various indirect methods have been recommended for discovering its presence. One of the best consists in neutralizing the solution, if acid, with potassa, and evaporating nearly to dryness; then adding a few copper filings, and heating the mixture with a little sulphuric acid. The copper combines with a portion of the oxygen of the nitric acid, and decomposes it, while characteristic red fumes of binoxide of nitrogen show themselves, if nitric acid be present. A still smaller quantity of the acid may be detected by substituting a crystal of protosulphate of iron for the copper, before adding the sulphuric acid; on the application of a gentle heat in this case, the characteristic action consists in the formation of an olive-green solution, the color of which disappears on boiling. The nitrous acid gas, formed by the deoxidising action of one portion of the ferruginous salt, dissolves, with the distinctive green color, in the solution of the unoxidised part of the salt. If a few drops of hydrochloric acid be added to a solution which contains free nitric acid, or a nitrate dissolved, the liquid acquires the power of dissolving gold leaf. This effect, however, is produced by hydrochloric acid in solutions of the iodates, chlorates, and bromates, but the presence of these salts may be detected by other characters. PRICE's test for the detection of iodine, and which is described at page 403, is equally applicable for the detection of nitric acid.

QUANTITATIVE ESTIMATION.—MARTIN separates the ammonia present in the substance to be examined from the nitric acid, by boiling it with potassa. He then introduces the resulting solution into a vessel, with metallic zinc, and a sufficient quantity of water, and adds by degrees hydrochloric or sulphuric acid. By these means the nitric acid is completely converted into ammonia, and its amount may now be arrived at by the usual methods for estimating that alkali, Vol. I., page 198. Seventeen of ammonia, NH₃, represent fifty-four of nitric acid, NO₅.

Nitrates.—Nitric acid combines with one equivalent of the various bases to form the class of salts termed nitrates. No acid nitrates exist or have been produced, but several subnitrates may be formed; that is to say, salts may be obtained containing more than one base for each equivalent of acid; such, for instance, as the subnitrate of copper, $3 \text{ Cu O, NO}_2, \text{HO}$. When heated, most of the nitrates fuse readily; at an elevated temperature they are all decomposed, and in most cases the pure oxide remains. When thrown on glowing coals, the nitrates are decomposed with scintillation; if dissolved in water, and paper be moistened with the solution, allowed to dry, and then burned, the smouldering combustion characteristic of touch-paper will be produced. This property, however, is also exhibited by the salts of some other acids, of which the chloric is the most important.

Adulterations.—The specific gravity of nitric acid is very often artificially augmented by dissolving in it nitrate of potassa; this sophistication, however, is very easily detected by evaporating the acid, when the nitrate so added will be left behind. But the best way of determining the real value of nitric acid is by ascertaining its saturating capability, that is, finding how much pure carbonate of soda it will neutralize.

The nitric acid of commerce is ordinarily contaminated by *sulphuric* and *hydrochloric acids*, or by *chlorine* or *chlorides*.

The presence of sulphuric acid is discovered by diluting a portion of the nitric acid with pure water, and adding a solution of nitrate of baryta; if this produces a white precipitate, insoluble in water, in acids, and likewise in ammonia, it is sulphate of baryta, and it indicates, of course, the presence of *sulphuric acid*. If the precipitate is in ponderable quantities, it should be first boiled with the acid liquor in which it has been produced, allowed to settle, filtered, washed, dried, ignited, and weighed: 116.5 grains represent forty of dry sulphuric acid.

The presence of *chlorine* or of *chlorides*, or of *hydrochloric acid*, is detected by diluting the nitric acid with pure water, and adding a solution of nitrate of silver. If a white curdy precipitate, or an opaline tinge or turbidity is produced, insoluble in nitric acid, but which instantly disappears by pouring an excess of ammonia, and reappears by adding an excess of acid, it is chloride of silver; in which case the acid liquor should be moderately heated, in order to promote the settling of the precipitate, which may then be collected on a filter as small as possible, washed, and carefully exsiccated. It should then be introduced into a counterpoised porcelain crucible; the filter, being scraped clean, is afterwards burnt upon the cover of the crucible, and the ashes are added to the precipitate in the crucible; the mass is then fused, and on cooling, it is weighed; 143.5 grains of chloride of silver represent 35.5 grains of chlorine, or 36.5 grains of hydrochloric acid.

Before testing the acid, as just said, it must not be forgotten to dilute it with three or four times its bulk of distilled water, for otherwise a precipitate would be produced, but which is nothing else than nitrate of baryta and nitrate of silver, which might simulate the presence of sulphuric acid and of chlorine. Such pre-

cipitates, however, immediately disappear by an addition of water.

When nitric acid contains fixed substances, they are easily detected by evaporating a small quantity of the acid in a watch-glass or small capsule, in which case a fixed residuum will be left. Pure nitric acid is entirely volatilizable by heat.

Impure nitric acid can always be easily purified by adding to it a sufficient quantity of nitrate of silver, in order to precipitate the chlorine and sulphuric acid, decanting the acid from the precipitates produced, and distilling it in a glass retort and glass receiver, taking care not to use either lute or cork. If done with care, and at a moderate heat, the acid which passes is pure and colorless.

Physiological Effects.—The action of this acid varies with its degree of concentration or dilution. In the concentrated form, the acid acts as a powerfully corrosive poison, which property it partly derives from its affinity for water, but more especially from the facility with which it gives out oxygen; so that the appearances caused by its action on some of the tissues are different from those produced by sulphuric acid. The permanent yellow stain—xanthoproteic acid—which it communicates to the cuticle, is peculiar to it. Iodine stains the skin yellow or brown, but a little caustic potassa quickly removes the color, when recent; whereas the yellowish stain caused by nitric acid becomes orange, on the addition of an alkaline soap. Bromine also stains the skin yellow; but, when recently produced, the color may likewise be removed by potassa. The yellow or citron tint communicated to the lining membrane of the tongue, pharynx, *et cetera*, by nitric acid, has been lucidly illustrated by Dr. ROUPELL. A preparation presenting appearances in every way identical, is preserved in the anatomical museum of the metropolitan hospital. Nitric, like sulphuric acid, also chars the animal tissues; and thus, after the ingestion of it, the stomach is sometimes found blackened, as if sulphuric acid had been swallowed. The symptoms are the same as those produced by sulphuric acid. The yellow, citron, or orange spots sometimes seen on the lips, chin, or face, will, when present, at once indicate the kind of acid swallowed. Sometimes the binocide of nitrogen is evolved by the mouth.

Properly diluted, nitric acid produces effects similar to those of the other mineral acids. It is said, however, to act less evidently as a tonic, and to be more apt to disagree with the stomach, so that it cannot be used for so long a time. In some instances it has excited pyalism, and from this circumstance, as well as from the occasional benefit derived from its use in the venereal disease, it has by some writers been compared in its operation to mercury—a comparison founded on theoretical rather than practical considerations.—*Pereira*.

OIL.—*Huile*, French; *Oel*, German; *Oleum*, Latin. —Oils are a very interesting class of natural substances, inflammable, and greasy to the touch. Oily bodies are generally divided into two classes, fixed or fat oils, and essential or volatile oils. The two are, however, entirely dissimilar, both in properties and composition;

indeed, except in the one common property of greasiness, they are not at all allied to each other. The oils belonging to one classification may readily be distinguished from those of the other; the essential oils emitting at ordinary temperatures a distinctive, intensely odorous, and penetrating vapor, and when dropped on paper, not producing a permanent greasy spot, while the stain of a fixed fatty oil does not disappear by exposure, nor even when the paper is subjected to a gentle heat. For the present, to avoid confusion, only the fixed and fat oils will be considered.

Fats and fixed oils are most indispensable requisites of domestic economy, equally important as nourishment, as material for the manufacture of soap, and as sources of light. They contain a very large proportion of carbon, as compared with that of the other constituents—a character that distinguishes this class of substances from the greater number of compounds of organic origin. In many instances the amount of carbon is from seventy to eighty per cent., and upon this property depends their great value as food, and as sources of light. As regards the former, they must always be most useful; those fats only which are unfit for food are valuable as sources of light, or for the production of soap.

HISTORICAL NOTICE.—Oils have been known from the earliest ages of the world, and were, even at that remote period, applied to a variety of purposes, but principally as a means of illumination. In the writings of MOSES olive oil is frequently mentioned; and it appears probable that the candlesticks so frequently referred to in Holy Writ were intended as a support for lamps, and not candles. In Genesis MOSES speaks of a *burning lamp*, and in the two following books it is clearly stated that olive oil was the material used as the source of light. The introduction of oils into Europe dates also from a very remote age. According to HERODOTUS, the Greeks were the first European people acquainted with them. They derived their knowledge of oil, and the means of procuring it, from the Cecrops, who brought olive oil from Sais, a province of lower Egypt. No record can be found showing the method of extracting it at this early date, nor even the purposes for which it was used. The Greeks of that period appear to have been ignorant of the mode of applying it as a source of light, for HOMER mentions wood torches as a means of illumination in use at the time of the Trojan war. EUSEBIUS, however, relates that, at the commencement of the fourth century, the city of Constantinople was annually illuminated on Easter eve by means of *lamps* and wax candles. Afterwards, until the introduction of tallow and animal fats, wax and pitch were the combustible materials most commonly employed.

SOURCES.—Oils are found abundantly in the vegetal and animal kingdoms. In the former, they occur in various parts of the plant, principally in the cellular structure of, and in the fleshy pulp surrounding the seeds, and very rarely in the roots. They are contained in that part of the seed which gives birth to the cotyledons, and not in the plumula or radicle. In the olive tree only the oil is contained in the fleshy integuments of the fruit. The seeds richest

in oil are those belonging to the genus *cruciferae*, and next to that are the *drupaceae*, *aomentaceae*, and *solanee*. Linseed contains twenty per cent. of oil, rape seed from thirty-five to forty, castor seed sixty per cent., and nuts about half their weight. The quantity of oil furnished by seeds varies, not only with the species, but in the same seed, with climate and method of cultivation. The seeds should be ripe, fresh, and of good quality. The yield of oil is always less than that actually contained in the seed, and the quantity remaining in the *marc* or pressed cake is greater in proportion as the starchy, ligneous, and albuminous principles predominate. The exact quantity of oil contained in seeds is easily estimated by taking a given quantity and bruising and treating repeatedly with ether, until the oil is completely extracted. The solution is then evaporated by means of a water bath, and the oily residue remaining is washed with water, to remove soluble matters, then dried and weighed, and the result is the exact proportion of oil present in the seed.

The part of the plant in which fats and oils are originally produced, is, according to DUMAS, the green leaves only, whence they are removed by a process of circulation, and deposited in the seeds and fruits. The essential ultimate constituents of oils are carbon, hydrogen, and oxygen, and consequently they may be produced by a process of deoxidation from carbonic acid and water, which are of course imbibed for the most part by the green leaves. It is, therefore, extremely probable that the theory of DUMAS, which attributes the assimilation or process of formation of oils to the verdant foliage of the plant, is the correct one; certainly it is the only plausible one yet adduced to explain this very peculiar action. The living plant breathes, feeds, and digests, exactly as is the case with the animal, though in the plant the organs of digestion and respiration exist almost entirely in the leaves; and here the vital force, under the influence of light, effects the transmutation of the food into the several substances of which the plant is constructed, while the whole, or at least the greater portion of the oxygen of the absorbed carbonic acid, is returned by respiration to the atmosphere. The formation of vegetal oils is, therefore, owing to absorption and transformation of food containing the elements under the form of gases, which by the vital force, and the peculiar organic structure of the plant, are secreted and arranged into entirely new products.

In animals, fats are contained chiefly in the cellular membrane, and, for the most part, immediately beneath the skin; also interiorly, particularly in the omentum, and in the region of the kidneys. This substance exists in the form of globules or small drops, and swims in the animal fluid with which the cells are filled. In the species of whale, the bony cavity of the head is the depository of the secreted spermaceti, and in the case of butter, the fat is mixed in a liquid state in milk. Oils and fats, both in plants and animals, are always associated with an albuminous principle; in vegetals, with *diastase*, *synaptase*, or an analogous body, which, from its peculiar liability to change, exercises an important influence upon the oils when kept for any length of time.

Two distinct theories concerning the production of animal fats have been promulgated, and each of them has had a large number of supporters, eminent for their extensive chemical knowledge.

DUMAS is of opinion that fatty matters are not generated in the animal body, but that they are derived, already formed, solely from the vegetable kingdom, the manifold products of which serve as food for the *herbivora*, while the *carnivora* also derive them indirectly from the same source, through the plant-eating animal. This opinion has for its supporters, BOUSSINGAULT, PAYEN, and others. Undoubtedly the fat of the *herbivora* is, to a certain extent, conveyed to them in the plants which serve them as food; while, at the same time, it is indisputable that fat may also be produced by a process of deoxidation of the amylaceous constituents of food. This latter theory was advanced by LIEBIG, and is now almost universally acknowledged to be the true explanation of the formation of animal fats. A powerful argument in favor of the latter supposition is, that the *carnivora*, which, as their name implies, are flesh-eating animals, have much less fat, but more muscle, than the *herbivora*. The latter derive the substance of their bodies from plants, to the amylaceous, or saccharine, starchy, and gummy components of which are due the production of fat; the comparatively small nitrogenized portion being taken up to form muscle, and the other albuminous or nitrogenous parts of the structure. The absence of the non-nitrogenous or amylaceous ingredients in the food of animals occasions a leanness of flesh, while at the same time, it is well known that the proportion of fat in the animal body may be increased by an augmentation in the quantity of non-nitrogenous food. A curious fact in support of LIEBIG'S theory was adduced by HUBER and by GUNDELACH, who fed bees *solely on pure sugar*, and found an abundant secretion of wax,—a true fat. No doubt, therefore, these insects produce wax by a process of assimilation of the sugar contained in honey: indeed, this has since been admitted by DUMAS. Animal fat may, therefore, be considered to be a product of the deoxidation of the non-nitrogenous constituents of vegetal food, and consequent upon a deficient supply of oxygen to the body, this element being absolutely indispensable to the dissipation of these components of food. It follows, therefore, that farinaceous food, and abstinence from exertion, are promotive of the formation of fat, rest being a necessary condition, as during locomotion or other exertion, respiration is more frequent, and the supply of oxygen consequently more abundant, and by its agency the formation of fat is prevented: the amylaceous constituents of the food, undergoing a species of slow combustion, are entirely broken up, and expelled from the system in the form of carbonic acid and water,—the components of the atmosphere from which they were originally produced in the plant. The above exposition is an admirable illustration of the dependence of the animal upon the vegetal kingdom, and a very important instance of the economy of nature.

PROPERTIES.—The consistence of fatty matters is very variable—from that of extreme fluidity, as in the oil of almonds, to that of solid masses, as suet or butter.

Those obtained from warm-blooded animals are usually solid at ordinary temperatures; whilst fish oils, and those procured from cold-blooded animals, remain liquid; sometimes, however, the same plant as well as animal yields both varieties. The concrete vegetal oils, as that of cocoa-nut, are sometimes designated vegetal butters.

The value of oils as combustibles is greatly affected by their degree of fluidity. This is determined by the period required for a given quantity to flow through a funnel of known dimensions. With an apparatus similar to that represented in Fig. 387, Vol. I., page 704, SCHUBLER and URE obtained the following results:—

Fluid.	Time required to flow through a given aperture. Seconds.	Fluidity. Water = 100.
Water,.....	90	100.0
Olive oil,.....	195	46.1
Colza oil,.....	162	55.5
Oil of brassica napus,.....	159	56.6
Oil of brassica præcox,.....	148	60.8
Oil of brassica napo-brass,.....	142	63.3
Oil of brassica rapa,.....	136	66.1
Train oil,.....	450	20.0 Ure.

The specific gravity of oils and fats is always below that of water, and varies from 0.91 to 0.94 at 60°. The oils, of all fluids, expand the most by heat, and, indeed, in some cases to such a degree as to render it necessary, for the purposes of commerce, to know exactly the extent of this expansion. The following table, given by SAUSSURE, shows the density of several oils at different temperatures:—

	At 53°.	At 75°.	At 122°.	At 200°.
Nut oil,.....	0.928	0.919	—	0.871
Almond oil,.....	0.920	—	—	0.863
Linseed oil,.....	0.939	0.930	0.921	0.881
Castor oil,.....	0.970	0.957	—	0.908
Olive oil,.....	0.919	0.911	0.893	0.862

For every degree of Celsius the volume of olive oil increases, according to PREISSER, one twelve-hundredth, of rape oil one eleven hundred and twentieth, and of train oil one one-thousandth, so that one hundred measures of train oil at 32° Fahrenheit will become in summer at 68° Fahrenheit one hundred and two measures.

Common hog's lard at 60° has a specific gravity of 0.938 in its fluid state; at 122°, it is 0.892; at 155°, it is 0.881; and at 200°, 0.863. The specific gravity of oil increases also with its age; indeed, it may be remarked, that no accurate determination of the degree of purity of an oil can be deduced from its density, as there are frequent discrepancies in the same kind of oil, according to the locality where the plant was cultivated, and the varied modes of extracting the oil.

Fats and oils may be exposed to a considerably high temperature without suffering any important change; but at a heat of between 500° and 600° they are rapidly decomposed, and, therefore, will not admit of distillation. This property especially distinguishes the fixed from the essential or volatile oils, which may be distilled without alteration. The continued action of heat upon fat oils has a very remarkable effect. A little above 500° they assume a darker color, and evolve acrid and offensive vapors; and when further heated to about 600°, eliminate carbonic acid, and carbide of

hydrogen gases, accompanied by a peculiarly irritating substance termed *acrolein*, and also margaric and sebacic acids, and a variety of solid and liquid carbides of hydrogen. The result of the action of heat, however, is not always the same, but varies with the nature of the oil. The period at which these alterations occur has been improperly said to be the boiling point, the phenomena of apparent ebullition arising from the escape of the gases produced by the decomposition of the oil. When introduced in small portions into red-hot vessels, or what is the same thing, when the vapor of oils is made to pass slowly through a red-hot tube, they are almost entirely converted into volatile products, consisting principally of carbonic oxide, and gaseous, liquid, and vaporous hydrocarbons. This mixture constitutes *oil gas*, which in illuminating power is far superior to that of the best coal gas, and exceeds in this property three and a half times that of ordinary coal gas. For a detailed notice of this highly interesting and important subject—the manufacture of oil gas, and its application to lighting purposes—the reader is referred to the article *GAS*.

Olein, Stearin, Margarin, and Glycerin.—CHEVREUL, in the course of an extended examination of fixed oils, which he concluded about the year 1813, discovered them to consist of, for the most part, always two, and frequently three distinct compounds, united in the most variable proportions. These bodies are combinations of *oxide of glyceryl* with stearic, margaric, and oleic acids. For the sake of brevity, these compounds are named *stearin*, *margarin*, and *olein*, and it is upon the prevalence of one or other of these ingredients that the consistence of fat depends. When stearin predominates, the fat is firm and solid; if margarin be most abundant, the fat is less hard; while if olein is the chief principle, the oil is liquid at ordinary temperatures.

BRACONNOT, who investigated this subject about the same period, gives the following table of the results of his experiments, showing the centesimal proportion of solid matter contained in the oils and fatty bodies therein mentioned:—

	Solid matter in one hundred parts.	Degrees.
Cow's butter in summer, . . .	40 fusible at	134.5
Cow's butter in winter, . . .	65 —	134.5
Lard,	30 —	110.0
Ox fat,	76 —	141.0
Mutton suet,	26 —	123.8
Goose's fat,	32 —	111.2
Duck's fat,	28 —	125.5
Fat of turkeys,	26 —	113.0
Olive oil,	28 —	68.0
Oil of almonds,	24 —	42.8
Colza oil,	46 —	45.5

Fats, therefore, as taken from vegetal or animal bodies, are not homogeneous chemical combinations, but mixtures of such, which, taken singly, have all the properties of the fats themselves. By congelation at low temperatures, and pressure of the concrete mass, a separation of the oil ensues into a liquid and a solid portion. The former consists of olein, and the latter of stearin or margarin, or both. By pressure between folds of blotting paper, or in linen bags, a nearly complete separation of the olein is effected, and the solid stearin

or margarin remains. By heating the paper in water, the liquid olein may be obtained separate. Tolerably pure stearin may also be procured by boiling the natural oil with alcohol, in which stearin is nearly insoluble. Besides the above process for procuring olein by refrigeration, it may be obtained by boiling oil for some time with a small proportion of caustic soda or potassa, and treating the mixture with dilute alcohol, when the olein collects as an oily layer upon the surface of the liquid. For the preparation of olein, almond oil should be employed, as it contains a greater quantity of this principle than other oils. Stearin constitutes by far the greatest proportion of the solid components of fats and fixed oils. The properties of these ingredients vary with the nature of the respective oils, so that the sole difference does not consist in the variable proportions of the three bodies, but also in peculiarities of the principles themselves; as it has been found that, according to their source, they solidify at very different temperatures.

When oily seeds, such as almonds, walnuts, or poppy seeds, are crushed or pulverized, so as to break up the cellular tissue, and bring its various ingredients into intimate admixture with each other, the fatty bodies, which the seeds naturally contain as neutral compounds, are gradually resolved into fatty acids, with simultaneous liberation of a colorless, inodorous, and sirupy liquid. The latter is *glycerin*, and was called by SCHEELÉ, its discoverer, the sweet principle of oils. The change is owing to the presence of a peculiar albuminous body, previously mentioned as being always associated with oils. This nitrogenous matter, gradually decomposing, acts as a ferment, and produces the above alteration in the constitution of the oils, and, as PELOUZE has shown, is independent of any absorption of oxygen. When heated with the hydrates of the fixed alkalies, with the alkaline earths and other metallic oxides, in presence of water, decomposition also ensues, the oily acids combine with the alkali or metallic oxide used, yielding oleates, margarates, and stearates; the oxide of glyceryl with which these acids were united separating in chemical combination with a certain proportion of water, the product being *glycerin*. This peculiar principle—the base of oils—in consequence of its growing importance in the arts and manufactures, and particularly as an article of the *materia medica*, has been made the subject of a separate article, to which the reader is referred. The three substances constituting the proximate principles of fats and oils, have also been noticed under the article *CANDLE*, where full information as to the mode of preparation, properties, and uses, will be found, together with a description of the respective acids entering into their constitution. It may be mentioned, that although the three components of oils—olein, stearin, and margarin—are respectively compounds of oleic, stearic, and margaric acids with the basis of glycerin, simple mixture of the fatty acids with the glycerin does not reproduce the oil from which they were obtained, in consequence of the metallic base, in displacing the oxide of glyceryl, having given up a portion of its water to it, while the fatty acids, in the process of separation from the metallic oxide, have also

united with a portion of water. In fact, the united weight of the fatty acids and glycerin always exceeds by three or four per cent. that of the oil originally employed. The water absorbed so modifies the constitution of the acid and base as to prevent the re-formation of the fatty bodies, of which they are the essential constituents.

BERTHOLLET has, however, recently succeeded in reproducing the natural fats by a direct union of their acids with the base of glycerin. According to this chemist, stearic, margaric, and oleic acids, each form three compounds, by uniting with oxide of glyceryl; during combination, water is separated in each case, but there appears to be a doubt as to the accuracy of his determinations of the precise quantity of water liberated. BERTHOLLET's researches on this subject have been noticed at some length in the article on GLYCERIN.

Other Constituents.—In addition to the three neutral principles, stearin, olein, and margarin, of which at least two are always contained in oil, many oils and fatty bodies contain another or more substances analogous in composition to these bodies, but essentially different in their properties. Some, like those above named, are, by the action of suitable reagents—for example, when treated with hydrates of the fixed alkalies—resolved into a fixed fatty acid and glycerin; others, when similarly treated, yield glycerin and a volatile fatty acid, and it is to the presence of the latter that the peculiar and characteristic flavor and smell of the various fatty bodies are to be attributed. In the appended table are given the names of these peculiar principles, with the acids yielded by each, and, so far as they are known, the melting points of the fat and of the acid:—

FATS YIELDING FIXED ACIDS.

Melts at		Melts at
Laurostearin, . . . 113°	Laurostearic acid, $C_{24}H_{48}O_4$ —109°·4	
Cocosin, 716	Cocinic acid, . . . $C_{26}H_{52}O_4$ —95	
Myristin, 87·8	Myristic acid, . . . $C_{28}H_{56}O_4$ —120·2

FATS YIELDING VOLATILE ACIDS.

Butyrin,	Butyric acid, . . . $C_8H_{16}O_4$
Valerin, or Delphinin, . . .	Valerianic acid, . . $C_{10}H_{20}O_4$
Caproin,	Caproic acid, . . . $C_{12}H_{24}O_4$
Caprylin,	Caprylic acid, . . . $C_{16}H_{32}O_4$
Caprin,	Capric acid, . . . $C_{20}H_{40}O_4$
Hircin,	Hircic acid, . . . —
Sabadillin,	Sabadillic acid, . . . —
Crotonin,	Crotonic acid, . . . —
Ricinin,	Ricinic acid, . . . $C_{22}H_{42}O_4$ —70°

Of the above principles, many are unknown in the separate state, and are supposed to exist merely from the liberation of their fatty acids by the saponification of the natural fats, and subsequent treatment with acid.

Action of Alkalies on Oils—Soaps—Margaramid.—The combination of the fatty acids with alkaline and other bases gives rise to the production of soap, which

will be discussed in a separate article. It may suffice here to observe, that the compounds of the fatty acids with the fixed alkalies constitute soluble soaps; and, with the earthy and metallic bases, insoluble soaps. In the cases of oxide of lead and of zinc, they are termed *plasters*.

The action of ammonia upon the fixed oils differs from that of the other alkalies and metallic bases. If the emulsion obtained by agitating solution of ammonia with a fatty oil be, soon after being prepared, mixed with sufficient dilute acid to neutralize the ammonia, or if the mixture of oil with ammonia be exposed to the air, the volatile alkali after some time is completely dissipated, and the oil is reproduced in its original state. As already observed, simple admixture of glycerin with the fatty acids does not reproduce the oil yielding them; and, therefore, the reproduction of the oil unaltered, after expulsion of ammonia, is a proof that no combination of ammonia with the fatty acids had been formed. Prolonged contact of ammonia with oils in a closed vessel, however, gives rise to the formation of true salts of ammonia with the fatty acids, or ammoniacal soaps; but in addition to these, there is produced also a peculiar substance to which its discoverer, BOULLAY, has given the name of *margaramid*. It is an amide of the fatty acid, and may be obtained by treating the soap of ammonia with boiling water, by which means it is thinned out, but not dissolved, and on cooling, the greater portion congeals at the surface. The congealed mass is dissolved in boiling alcohol, and on cooling, margaramid is thrown down as a white, crystalline, perfectly neutral substance. The composition of margaramid is margarate of ammonia, *minus* two equivalents of water:—

Margaramid is unalterable in the air, insoluble in water, but readily dissolved by alcohol or ether. It fuses at 140°, burns with a sooty flame, is decomposed by boiling concentrated solutions of the fixed alkalies, and also by acids when at a certain degree of concentration. The transformation of oils into margaramid by the action of ammonia is especially rapid and characteristic in the case of castor oil.

Action of Acids on Oils—Sulphuric Acid.—The action of acids upon oils has been the subject of many recent critical examinations. The changes produced vary with the kind of acid employed. Sulphuric acid, when added to many oils to the amount of one per cent., has no action upon the oil itself, but it instantly develops a dark green or brownish coloration. After some time, a chemical combination of the acid with mucilage and other parenchymatous matter is deposited, and the oil is thus rendered brighter and more limpid. When sulphuric acid is added in larger quantities, very remarkable changes occur. In moderate proportion, its action appears to be limited to the abstraction of the oxide of glyceryl, with which it combines and forms bisulphate of oxide of glyceryl, or sulphoglyceric acid— $C_6H_7O_6 \cdot 2SO_3$, whilst the oily acids are set at liberty. When applied in larger quantities,

the result is the conversion of the fatty acids into various modifications, sulpho-glyceric acid being a simultaneous product. If sulphuric acid be gradually added in the cold to twice its volume of olive oil, the mixture becomes tough in appearance, and if, after standing twenty-four hours, two volumes of water be added, sulpholeic, sulpho-margaric, and sulpho-stearic acids separate and rise to the surface; for, though soluble in pure water, these acids are quite insoluble in the acid liquid. When the solution of these acids in water is kept for some time at ordinary temperatures, the sulphuric acid separates, and there are produced three new acids—metamargaric, metoleic, and hydromargaric acids. The two former rise to the surface, and the latter remains dissolved in the water along with sulphuric acid. On heating the original solution, there is formed a fourth, hydroleic acid, which rises to the surface in admixture with the acids above mentioned; and if this mixture is boiled with alcohol, still another acid is produced—the hydromargaric, which is deposited from the solution on cooling. FREMY was the first to notice these peculiar reactions; the subject has, however, since been investigated by others, and especially by MILLER and VARRENTTRAPP, but is still to a great extent involved in mystery. The sulpho-acids have an oily, bitter taste. Of the three, sulpholeic is by far the most permanent.

The action of sulphuric acid upon oils or fats at a high temperature, differs from the above; a separation of the fatty acids and oxide of glyceryl is immediately effected, and the glycerin and sulphuric acid mutually decompose, yielding sulphurous and carbonic acids. The application of this reaction to the separation of the fatty acids, for manufacturing purposes, has already been discussed in connection with the article CANDLE.

Action of Nitrous Acid—Elaidin.—The action of nitrous acid upon fixed oils varies with the kind on which it operates. According to their behavior under the influence of this acid, they are divided into two distinct classes or divisions—the *drying* and the *non-drying* oils. The latter by this treatment are converted into solid masses, a change of which those of the first division are not susceptible. The reaction appears to be confined to one of the principles of the greasy oils—olein; and its effect is to convert this, the most liquid of the components of oil, into a concrete fatty matter, termed *elaidin*, which by analysis is found to consist of a peculiar acid—elaïdic acid—in combination with oxide of glyceryl. This action was first observed by POUTET, a French apothecary, in the course of experiments on olive and other oils. BOUDET showed nitrous acid to be the true agent of decomposition. According to the quantity employed, the change is effected in a longer or shorter period of time. Thus, a mixture of three parts of nitric acid, with one of nitrous acid, gave the following results:—

1 part of the acid with 33 of olive oil solidified in 70 minutes.	
1 50	78
1 75	84
1 100	130
1 200	435
1 400	remained unchanged.

The annexed table indicates the time required, at

the temperature of 60°, for the congelation of one hundred grains of oil, when treated with three grains of nitric acid, and three of pure nitrous acid:—

	Color immediately developed.	Number of minutes before congelation.
Olive oil,.....	Bluish green,	73
Sweet almond oil, ..	Dirty white,	160
Bitter almond oil, ..	Deep green,	160
Nut oil,	Bluish green,	103
Castor oil,.....	Bright yellow,	603
Colza oil,	Brown yellow,	2400

The very small quantity required to produce the effect, and the remarkable fact, that in some cases a similar solidification is produced by a deoxidising agent—sulphurous acid—render this action a problem as yet unexplained. Protonitrate of mercury also induces a similar change on the greasy oils, and in all cases, with the exception of castor oil, the product of the action is the same. Pure elaidin is best obtained by agitating olive oil with a mixture of nitrous and nitric acid. To procure this mixed acid, one part of nitrate of lead is heated in a retort connected with a receiver, in which is contained one part of nitric acid, of specific gravity 1.35. To one hundred parts of olive oil are added ten parts of this mixture of acids, and the whole is agitated till it begins to solidify. It is then allowed to stand at rest, and gradually a yellowish semi-solid mass is formed. This, when washed with alcohol, becomes white, and after pressing strongly between folds of bibulous paper, and subsequent crystallization from ether, yields pure elaidin. As thus procured, elaidin is solid at ordinary temperatures, and when heated with alkalis or metallic oxides, is saponified. It fuses at a temperature between 90° and 100°, is almost insoluble in alcohol, but is readily dissolved by ether, and in all proportions. Its specific gravity is 0.8978, and by distillation it yields, among other products, acrolein, and elaïdic and sebatic acids. The stearin and margaric of fats are not transformed into elaidin, though this change is stated to occur by some chemists. According to GOTTLIEB, the production of elaidin is due solely to the conversion of oleic acid into an isomeric modification, but how the acids effect the transformation is still a matter for further research. A small quantity of ammonia is formed during the reaction—a proof of the decomposition of a portion of the acid. The drying oils, as those of linseed, poppy seed, and hemp, undergo no metamorphosis by the action of nitrous acid, except that they are slightly tinged brown. The composition of elaidin is exactly the same as the olein from which it is produced— $C_{150}H_{136}O_{14}$ —and consists of one equivalent of glycerin, and four of elaïdic acid, minus eight equivalents of water—

one equivalent of elaidin.

Elaïdic acid is prepared by saponifying elaidin, by heating it with a fourth of its weight of caustic soda or potassa, and half its weight of water. The resulting soap is a mixture of margarate and elaidate of potassa or soda, and when treated with hydrochloric acid, chloride of the metal of the alkali is formed, and a mixture of elaïdic and margaric acids liberated. According to MEYER, it may be obtained pure by passing

a current of nitrous acid, as disengaged by the deoxidation of nitric acid when heated in contact with starch, through pure oleic acid at a low temperature, and avoiding the use of an excess of acid. The liquid after a short time congeals into a crystalline mass. This is washed with hot water to remove nitric acid, and then dissolved in its own volume of hot alcohol. On cooling, elaidic acid is deposited as a mass of crystalline scales, which may be purified by pressure, re-solution, and recrystallization, from alcohol.

MORFIT gives a method for preparing this acid on the large scale. Oleic acid is to be treated with steam at a high temperature, and afterwards there is added exactly sufficient solution of carbonate of potassa to neutralize any sulphuric acid it may contain. After standing some time, the oil rises to the surface of the condensed steam, and must be siphoned off into a wooden tub. To every two thousand pounds is then added an intimate mixture of eighty-one pounds of nitric acid, of specific gravity 1.35, and thirteen and a half pounds of molasses, and the whole is very gently heated by steam passed in through a worm of copper, having its terminus above the kettle, as it is not desirable that any water should get into the oily matter at this stage of the operation. When red fumes begin to appear, the action must be checked by drenching with four or five hundred gallons of water, after which an aqueous solution containing forty to fifty pounds of acetate of ammonia is added. During all these operations, the mass should be constantly agitated, and, after the addition of water, very briskly for two or three hours. The water and agitation withdraw all acid matters, and leave the elaidic acid in a condition to be drawn off, after repose, into small tubs, and cooled. Neutral oils by the same treatment yield elaidin, and this latter, as well as elaidic acid, is an excellent material for the manufacture of soap and candles. Elaidic acid is a pearly crystalline solid, resembling in appearance the silvery scales of sublimed benzoic acid. It fuses at about 112° , is readily soluble in alcohol, less so in ether, and quite insoluble in water. When distilled, a great portion passes over unaltered, the remainder is decomposed into carbides of hydrogen, but no sebacic acid.

As already observed, GOTTLIEB has shown that elaidic acid is isomeric with oleic acid. Its composition is, therefore, $C_{36}H_{38}O_2$, $HO = C_{36}H_{34}O_2$. This chemist proved likewise, that a small quantity of freshly-prepared elaidic acid, when mixed with a large proportion of oleic acid, gradually converts the whole mass into elaidic acid; and also that when exposed to the air, elaidic acid gradually becomes oxidised to oxyelaidic acid $= C_{36}H_{34}O_3$, whilst oleic acid submitted to the same influence, gradually passes into $C_{36}H_{34}O_2$.

Action of Chlorine, Bromine, et cetera.—The fixed oils are decomposed by chlorine and bromine, yielding hydrochloric and hydrobromic acids. Compounds of the oil are also at the same time formed with those radicals, in which it frequently happens, that each equivalent of hydrogen abstracted is replaced by one of the halogen. Iodine is generally dissolved, forming a brown solution. Sulphur is also soluble in oils, and, if heated, rather largely; the greater portion, however, is deposited on cooling; but if the tempera-

ture of the mixture be increased to the point at which the oil begins to be decomposed, sulphide of hydrogen is evolved, and a permanent solution formed. This compound is not saponifiable, it mixes with the fat and volatile oils, and, when long exposed to the air, dries into an elastic substance, insoluble in ether. When distilled, among other products sulphide of hydrogen is evolved, and a black porous mass remains, containing centesimally forty-five of sulphur, and fifty-five of carbon, and is expressed by the formula— SC_3 . Phosphorus and selenium are also sparingly soluble in the fixed oils.

The action of steam at a high temperature upon fatty oils was investigated by TILGHMAN. He observed that when a mixture of fat and water is forced, under strong pressure, through tubes heated nearly to redness, so as to raise the temperature of the mixture to between 400° and 500° , the fatty matter is entirely decomposed into glycerin and fatty acids; the elements of water enter into combination with those of the fat, and by this means a result is obtained exactly the reverse of that produced by BERTHOLLET at lower temperatures, when the acid and base are caused to reunite, again producing the natural fat. The application of TILGHMAN'S discovery to the preparation of the pure fatty acids, has been treated of at length in connection with the article CANDLE.

Sebacic Acid.—It has already been observed that the fixed oils, when submitted to distillation *per se*, are decomposed, yielding, besides carbonic acid, inflammable gas, and various hydrocarbons—*margaric* and *sebacic* acids, and a substance termed *acrolein*. A portion of oleic acid also passes over unchanged. Sebacic acid, with the exception of castor oil, is yielded by all oils, whether animal or vegetable, drying or non-drying oils. It is formed exclusively from the decomposition of oleic acid. Stearic and margaric acids, as well as pure margarin and stearin, do not yield a trace of it. The detection of sebacic acid amongst the products of this decomposition is, therefore, a certain test of the presence of an oil, and especially of olein or oleic acid. As produced from oleic acid, it is accompanied by a considerable quantity of capric and caprylic acids, with traces of valerianic and butyric acids. To obtain it pure, the whole liquid and solid products of the distillation of oils or fats, or better, of pure olein or oleic acid, are boiled with water, until the soluble portion is extracted. The aqueous liquid deposits sebacic acid on cooling. The crystals are purified by washing with cold water, and recrystallizing from the hot solution, till they become colorless, and free from empyreumatic smell. Or the watery solution is precipitated by adding acetate of lead, which throws down sebate of lead. This, after washing, is dried; and, decomposed by dilute sulphuric acid, yields a solution which, on evaporation, deposits pure crystals of sebacic acid. According to DUMAS and PELIGOT, its ultimate composition is as annexed:—

	At weight.	Centesimally.
10 Eqs. of carbon,.....	60	59.4
9 Eqs. of hydrogen,.....	9	8.9
4 Eqs. of oxygen,.....	32	31.7
1 Eq. of sebacic acid,.....	101	100.0

As thus obtained, the acid is combined with one equivalent of water, and is, therefore, expressed by the formula, $C_{10}H_8O_3, HO$. Hydrated sebacic acid forms light, white, pearly scales, resembling benzoic acid in appearance; indeed, it was considered by BERZELIUS to be identical with this acid. It has a very slightly acid taste, but reddens litmus. It fuses at 260° to an oily liquid, and, at a higher temperature, sublimes unchanged. It is much more soluble in hot than in cold water, and is readily dissolved by alcohol or ether. With the alkalies it forms soluble sebrates, but its salts, with other metallic oxides, are for the most part insoluble. LIEBIG and REDTENBACHER were the first to notice this acid as a certain and delicate test of the presence of oleic acid.

Acrolein.—Acrolein is another highly characteristic product of the decomposition of oils by the application of a high temperature. When the volatile products arising from the destructive distillation of oils or fats, are passed through a series of bottles, half filled with water, the second and third bottles retain the greater portion of the acrolein, partly in solution in the water, and partly in the form of an oil floating on the surface of the liquid. When this floating oil is agitated with twenty times its bulk of water, the greater part of it is dissolved; and when this solution is distilled in a water bath, an oily matter—nearly pure acrolein—passes over at about 125° . According to REDTENBACHER, it is most readily obtained in a state of purity by distilling, in a capacious retort, a mixture of glycerin with anhydrous phosphoric acid, or bisulphate of potassa; the vapors are condensed in a receiver placed in a freezing mixture. The receiver is luted on to the retort, and is provided with a tube conducting into a chimney with a good draught, so as to carry off any uncondensed acrolein. To exclude atmospheric air, the oxygen of which rapidly combines with acrolein, the whole apparatus must be charged with carbonic acid, and the current be continued to the end of the process. The distillate separates into two layers, of which the upper one consists of acrolein, and the lower one of an aqueous solution of the same substance, and containing also another body resulting from the oxidation of acrolein. The latter is acrylic acid, very analogous to acetic acid, and is produced during the distillation, even in the presence of carbonic acid. The distillate, with the addition of a quantity of powdered litharge, to retain acrylic acid, is rectified by the heat of a water bath, and the acrolein thus obtained is submitted to another rectification from chloride of calcium, and is then as pure as it has yet been obtained. Acrolein is especially remarkable for the peculiarly pungent and acrid nature of its vapor, intensely disagreeable and irritating to the eyes and nose, the evaporation of even a few drops, in a large room, causing a copious flow of tears in the eyes of all present, and with severe pain. It is a colorless, limpid, and volatile oily liquid, possessing a high refracting power, is very soluble in ether, and sparingly so in water. It boils at 125° . It is assumed to be the hydrated oxide of a radical termed, *acryl*— C_6H_3 , and its formula is C_6H_3O, HO . When long kept, it changes spontaneously into a white, flocculent, inodorous substance,

which REDTENBACHER named *disacryl*. The latter body is insoluble in ether, oils, acids, and alkalies. As it is formed even when acrolein is excluded from air, it is in all probability an isomeric modification of this body. The aqueous solution of acrolein also gradually undergoes a similar change. Sometimes acrolein, under the same circumstances, becomes transformed into a resinoid mass, which fuses at 212° , and forms a brittle transparent mass, on cooling. This substance is insoluble in water, but soluble in alcohol and in solutions of the alkalies. Acrolein owes its formation solely to the decomposition of glycerin, and its production is, therefore, an extremely sensitive test of the presence of the latter body. It appears to be produced by a dehydration of glycerin, since this substance contains the elements of acrolein, *plus* four equivalents of water.

Acrolein and its products of oxidation are remarkably analogous to aldehyde and its products, as will be observed by a comparison of the subjoined tables:—

Acryl,.....	C_6H_3 —unknown.
Hydrated oxide of acryl—acrolein—	C_6H_3O, HO .
Acrylous acid,.....	$C_6H_3O_2, HO$.
Acrylic acid,.....	$C_6H_3O_3, HO$.
Acetyl,.....	C_4H_3 —unknown.
Hydrated oxide of acetyl—aldehyd—	C_4H_3O, HO .
Acetous acid,.....	$C_4H_3O_2, HO$.
Acetic acid,.....	$C_4H_3O_3, HO$.

It may be observed that STENHOUSE found in palm oil, and PLAYFAIR in butter of nutmegs, a base having the same formula as acrolein— $C_6H_4O_2$. This substance, however, when separated from the oily acid, always appears as ordinary glycerin.

Elementary Composition of Oils.—From what has been detailed as to the proximate constituents of oils, it will hardly be thought necessary to notice their elementary composition. Indeed, a knowledge of the ultimate analysis of any organic body, is only a very slight assistance to the chemist in the determination of the true composition of these substances. This can only be arrived at, to any degree of certainty, by a thorough investigation of the changes induced by the action of reagents, and an accurate determination of the quantities of the several products, as well as their composition. It is owing to the application of this principle, first laid down by the illustrious CHEVREUL, that, in the hands of such philosophers as LIEBIG, DUMAS, BOUSSINGAULT, BUNSEN, WÖHLER, and others, organic chemistry has made such rapid strides during the last half century. The Editor has, however, annexed a table, showing the relative centesimal proportions of carbon, hydrogen, and oxygen, in each of the following oils, together with the name of the authority:

	Carbon.	Hydrogen.	Oxygen.	Authority.
Olive oil,.....	77.21	13.36	9.43	{ Gay-Lussac and Thenard.
Almond oil,.....	77.40	11.48	10.82	Saussure.
Linseed oil,.....	76.01	11.35	12.62	Do.
Nut oil,.....	79.77	10.57	9.12	Do.
Castor oil,.....	74.17	11.03	14.78	Do.
Whale oil,.....	76.13	12.40	11.50	Bérard.
Spermaceti oil,.....	78.91	10.97	10.12	Ure.
Hog's lard,.....	79.09	11.14	9.75	Chevreur.
Suet,.....	78.99	11.70	9.30	Do.
Butter,.....	65.60	17.60	16.80	Bérard.

All fixed oils consist essentially of these three elements only, some, however, yield minute traces of nitrogen, referable to adhering impurities.

Drying and Non-Drying Oils.—Excluded from air, oils may be preserved unchanged for a lengthened period; but when exposed to the air, some oils, through the absorption of oxygen, become converted into a thick and viscid mass; others are changed into a transparent resinous body or varnish, especially when they are in thin strata. This reaction constitutes another well-marked distinction of the oils into the two classes, *non-drying* or *greasy* oils, and *siccative* or *drying*. The former class, though they may acquire more color and solidity, never lose their property of communicating a greasy stain, and the latter, as already mentioned, do not solidify when mixed with nitrous acid, or protonitrate of mercury. Oleic acid, as obtained from drying oils by absorption of oxygen, dries to a resinous mass, like the oil from which it is derived, and appears to be a distinct substance from the oleic acid of non-drying or greasy oils. The most important drying oils are those of linseed, poppy seed, grape seed, and nuts; and all are much more susceptible of the change after having been heated with the addition of a small quantity of oxide of lead. The principal non-drying oils are those of olive, colza, sweet almonds, rape seed, and palm oil. These, under the same circumstances, acquire rancidity, become thick and less combustible, and assume an offensive smell, more especially when they contain much impurity, such as albumen or mucilage.

SAUSSURE has particularly investigated this action of air or oxygen on oils, and has announced the phenomena occurring during exposure as follows:—He found that the recently-expressed fixed oils are scarcely affected by the oxygen of the atmosphere, but that after a variable period, sometimes of several months, but dependent upon temperature and exposure to light, they begin rapidly to absorb oxygen, and evolve hydrogen and carbonic acid gases. SAUSSURE's experiment to prove the absorption of oxygen by oil was the following:—A layer of nut oil, one quarter of an

inch thick, and three inches in diameter, was inclosed in oxygen gas standing over quicksilver. During eight months, from December to August, the oil absorbed only three times its bulk of gas, but in the course of ten days in the latter month, it absorbed sixty additional volumes. This absorption of oxygen diminished progressively, and at the end of three months, entirely ceased, and the oil had taken up one hundred and fifty-five times its bulk of the gas. No water was generated, but twenty-two volumes of carbonic acid were disengaged, and the result was a transparent jelly, which did not produce a stain on paper. Linseed oil, in undergoing this metamorphosis, does not evolve any gas. Under certain circumstances, the alteration by the action of oxygen may become so energetic as to lead to a considerable elevation of temperature, and ultimate inflammation, and particularly if the surface of the oil is greatly extended, as in the case of oily wool or hemp, or greasy cloth, which, when left in a heap, has frequently taken fire spontaneously, and caused the destruction of mills, warehouses, and ships; indeed, so frequently has spontaneous combustion arisen from this circumstance, causing lately the almost total destruction of one of the noblest of British merchantmen, as to render precaution necessary in all cases where danger can arise from such causes. In illustration of these occurrences, it may be proved experimentally that if paper, linen, tow, wool, cotton, or bodies of a like nature, be slightly imbued with linseed or hempseed oil, and placed in contact with sun and air, especially when in heaps or piles, they will quickly inflame. This spontaneous combustion is owing to rapid absorption of oxygen by the oil, the hydrogen of which is inflamed by the caloric eliminated from the gas at the moment of its absorption, until then existing as latent heat, and serving to retain the oxygen in its gaseous condition.

Enumeration of Vegetal Greasy Oils.—The subjoined is a list of the principal greasy oils of commerce, with the plants that yield them, their specific gravity, and the per centage amount of oil that may be extracted from some of the seeds mentioned:—

	Plants.	Specific gravity.	Yield of oil per cent. From olives.
Olive oil,.....	Olea Europea,.....	0.9176	32
			From seeds.
Rape seed oil,.....	Brassica campestris et napus,.....	0.9136	30 to 36
Colza oil,.....	Brassica campestris oleifera,.....	0.9136	36 to 40
Summer rape seed oil,.....	Brassica præcox,.....	0.9390	36 to 40
Almond oil,.....	Amygdalus communis,.....	0.9180	28 to 54
Cocoa-nut oil,.....	Cocos nucifera,.....	—
Palm oil,.....	Cocos butyracea vel avoira elais,.....	0.9680	—
Teel oil,.....	Sesamum orientale,.....	—	40
Oil of behen or ben,.....	Guilandina mohringa,.....	—	—
Beech oil,.....	Fagus sylvatica,.....	0.9225	15 to 17
Oil of mustard,.....	Sinapis nigra et arvensis,.....	0.9160	15 to 38
Plum kernel oil,.....	Prunus domestica,.....	0.9127	33.3
Butter of cacao,.....	Theobroma cacao,.....	0.8920	—
Laurel oil,.....	Laurus nobilis,.....	—	—
Ground nut oil,.....	Arachis hypogæa,.....	0.9242	60
Pincy tallow,.....	Vateria Indica,.....	0.9260	—
Oil of radish seed,.....	Raphanus sativus oleifera,.....	0.9187	50
Cherry-stone oil,.....	Prunus cerastus,.....	0.9239	—
Apple seed oil,.....	Pyrus malus,.....	—	—
Spindle-tree oil,.....	Euonymus Europeus,.....	0.9380	—
Cornel-berry-tree oil,.....	Cornus sanguinea,.....	—	—
Oil of the roots of cyper grass,.....	Cyperus esculenta,.....	0.9180	—
Henbane seed oil,.....	Hyoscyamus niger,.....	0.9130	—
Horse-chestnut oil,.....	Æsculus hippocastanus,.....	0.9270	2 to 8

Characters of the Drying Oils.—The drying oils vary from those just enumerated, by becoming gradually converted into solid masses by exposure to the atmosphere, and also by not being solidified by contact with nitrous acid or protonitrate of mercury. Their principal use is in the preparation of varnishes and painters' colors, and the more quickly they become hard by exposure, the more valuable are they for these purposes. Their siccative properties may be much increased by heating them with about seven or eight per cent. of their weight of litharge, which, in this proportion, is, for the most part, dissolved by the oil. The heat is continued until the oil acquires a reddish hue. Oxide of manganese, oxide and sulphate of zinc, and magnesia, have also been used to produce a similar effect; what is technically known as *boiled* oil, being linseed oil which has been thus treated. According to CHEVREUL, the common practice of heating the oil to a very high degree, and for a considerable length of time, is not essential to the production of a good drying oil; linseed oil heated to 140°, with the addition of ten per cent. of its weight of oxide of manganese, having acquired powerful siccative properties. LIEBIG is of opinion that the increased rapidity with which oils thus treated become hard on exposure, is owing to the separation of the mucilaginous and other matters, by the oxide of lead, and that the atmospheric oxygen is thus brought more closely into contact with each particle of oil. DUMAS and others consider the effect to be due, in a great measure, to the presence of oleate and stearate of lead dissolved in the oil. Another view, which the Editor, however, considers fallacious, supposes the conversion of the oil into varnish to be the result of the saponification of the fatty acid by means of oxide of lead, and the simultaneous destruction of the oxide of glyceryl by the agency of heat. But if linseed oil be saponified in the ordinary manner, and the soap produced be afterwards decomposed by means of an acid, so as to separate the whole of the glycerin, and as much oxide of lead be then dissolved in the fatty acid as will allow the mass to remain fluid on cooling, no varnish is obtained, and this is positive proof that the destruction of the oxide of glyceryl is not the object of the manufacture of quick drying oils. If a previous remark be borne in mind, that the drying oils, as shown in the experiments of SAUSSURE, absorb oxygen from the air with much greater rapidity at a later period, than when first exposed, it will appear probable that one or other of the foreign matters present retard the absorption, and this being dissipated after a

long resistance, the oil is brought more freely into contact with oxygen. The formation of varnish is thus reduced to a simple purification of the oil, by removing all those substances which prevent the immediate contact of the oil with atmospheric oxygen. Adopting this highly probable assumption, LIEBIG devised a method for removing the mucilaginous impurities by precipitation at the ordinary temperature. He recommends for the production of a superior and less colored drying oil, that the oil be agitated for some time with a mixture of water, litharge, and subacetate of lead, without the application of heat. In prosecuting this method, the basic acetate of lead is first prepared as follows:—One part of neutral acetate of lead is dissolved in five parts of water, and to the solution is added one part of finely reduced litharge. The whole is allowed to digest until the red of the litharge has been replaced by a white color. The clear solution of basic acetate is then decanted, and mixed with an equal quantity of water, and added to twenty parts of linseed oil, which has previously been triturated with one part of finely powdered litharge. The mixture now requires to be shaken at intervals, and subsequently allowed to remain at rest for some hours, when the impurities subside with the water, and the supernatant oil is so pure that it dries into a varnish in twenty-four hours. In this case, a small quantity—four to five per cent.—of oxide of lead is retained in solution by the oil; but contrary to its effect, after being boiled with the oil, it improves, rather than deteriorates, the varnish produced. Should it, however, in any way interfere with the uses to which the oil is to be applied, it may easily be removed by agitation with dilute sulphuric acid. The solution of acetate of lead employed in the above method of purification, and which collects below the stratum of oil, may be again used in the preparation of the subacetate, by the addition of litharge as before.

The oil or varnish taken for the preparation of printers' ink, is procured by boiling drying oils in an earthenware vessel. After ebullition for a sufficient length of time, the vessel is removed from the fire, and uncovered, when the vapors inflame. It is allowed to burn for about half an hour, then extinguished by replacing the cover, and again seethed until it acquires the proper consistence, and the tendency to dry quickly.

Enumeration of Drying Oils.—The following is a list of the principal drying oils, with their sources, specific gravity, and the per-centage yield of some of the seeds:—

	Plants.	Specific gravity.	Centesimal yield.
Linseed oil,	<i>Linum usitatissimum et perenne</i> ,	0.9347	11 to 22
Nut oil,	<i>Corylus avellana et juglans regia</i> ,	0.9260	60
Poppy oil,	<i>Papaver somniferum</i> ,	0.9243	56 to 63
Hempseed oil,	<i>Cannabis sativa</i> ,	0.9276	14 to 25
Castor oil,	<i>Ricinus communis</i> ,	0.9611	25
Grape seed oil,	<i>Vitis vinifera</i> ,	0.9202	—
Cucumber oil,	<i>Cucurbita pepo et melapepo</i> ,	0.9231	—
Sunflower oil,	<i>Helianthus annuus et perennis</i> ,	0.9262	15
Tobacco seed oil,	<i>Nicotiana tabacum et rustica</i> ,	0.9232	—
Oil of julienne,	<i>Hesperis matronalis</i> ,	0.9281	18
Oil of camelina,	<i>Myagrum sativa</i> ,	0.9252	28
Oil of weld seed,	<i>Reseda luteola</i> ,	0.9358	—
Oil of cress seed,	<i>Lepidium sativum</i> ,	0.9240	56 to 58
Oil of deadly nightshade,	<i>Atropa belladonna</i> ,	0.950	—
Oil of cotton seed,	<i>Gossypium barbadense</i> ,	—
Pinetop oil,	<i>Pinus abies</i> ,	0.9285	—

Extraction of Oils from Seeds.—The vegetal oils are for the most part obtained by expression, the seeds being previously ground or bruised. Some seeds after this treatment readily yield to pressure, and give what is known as virgin oil, possessing an agreeable taste; others, especially those containing a large proportion of mucilaginous matters, give up their oil with great difficulty, and it becomes necessary to submit the bruised seeds to torrefaction, previous to pressure. The albumen is thus coagulated, and the oil, rendered less viscous, becomes more easy of separation. The latter process, however, requires careful management, or the oils are greatly impaired, both in color and taste.

Until a comparatively recent date, the treatment of oleiferous seeds for the extraction of their oil was by pounding in hard wooden mortars, with pestles shod with iron, and set in motion by cams driven by a shaft turned with horse or water-power. The bruised seed was then transferred to woollen bags, which were wrapped in horse-hair cloth, and squeezed between upright wedges in press-boxes. This arrangement, known as the Dutch mill, has been almost entirely superseded by the hydraulic oil mill and press. In some districts, however, both in this country and on the continent, the old method is still obstinately adhered to, and supposed to be preferable to the hydraulic mills and presses. Some varieties of seed, such as linseed, rape, and other hard seeds, require, before the final crushing, to be passed between iron rollers, in order to crack the shells. The seeds are first introduced into a hopper, through which, by means of a fluted roller, lying across it, they are caused to descend equably between the crushing rollers. These rollers revolve in opposite directions, and are sometimes of different sizes, so that different velocities may be given to their surfaces, enabling them also to draw in different sizes of seed, and to perform their work more quickly. Two scraper blades, are pressed by means of two weights, hanging upon levers, against the surface of the rollers, and remove any seed-cake that may adhere to them. The crushed seeds fall through a slit in the case, and are received into a chest placed upon a board beneath.

The seed broken by the rollers is passed under two vertical granite millstones or runners—Fig. 375—revolving on a horizontal bed. For accelerating the pulverization, a blade should be attached, and revolve with the stones, for turning up the mass and detaching that which adheres, and returning it constantly into the track of the runners. The two stones, travelling round their circular path, grind the seeds, not merely by their weight, but also by a rubbing motion or attrition; for their periphery being not conical, but cylindrical, they cannot roll on a plane surface without at every instant turning round with a certain amount of friction upon their resting points. Some manufacturers employ stones hooped with iron; but the rough granite surface is much the best. It may be dressed from time to time with hammers as it becomes irregular.

In some cases, and especially when operating upon old seeds, a small quantity of water is added previous to the final crushing, which, taking the place of the oil in the seed, renders the process of extraction much

more easy of execution; sometimes, however, this addition would be injurious. Occasionally, also, the seeds are subjected at once to the runners, dispensing entirely with the previous crushing. When the seed is sufficiently bruised by either or both of these operations, the pasty mass is generally heated in iron pans over an open fire, although the practice is by no means judicious. The object of doing so is principally to coagulate the albumen, which otherwise either retains a large quantity of oil, or itself exudes in admixture with the expressed oil. By heating the bruised seed, the oil is also rendered more limpid, and therefore more easily expressed. The heat of boiling water, however, is sufficient, and either this or steam may be advantageously applied to effect the above purposes; the uniform action of the latter upon the heated pan obviating completely the evils arising from partial and overheating, which always occur at the top and bottom of the common pans.

Fig. 372 is an apparatus designed for this purpose, shown in vertical section. It is known as the steam-kettle of HALLETTE. *a* is the wall of masonry, upon

which and the iron pillar, *b*, the pan is supported. It is inclosed in a jacket for admitting steam into the intermediate space, *ddd*, at its sides and bottom. *c* is the middle of the pan, in which the shaft of the seed-stirrer, not shown in the figure, is planted upright, resting by its lower end in the step, *e*. *f* is an opening, by which the contents of the pan may be emptied; *g* is an orifice into which the mouth of the sack or woollen bag is inserted, so as to receive the heated seed when it is expelled by the rotation of the agitator, after the plug, *f*, is withdrawn; *h* is the steam induction pipe; and *i* the eduction pipe, which serves also to run off any condensed water that may collect.

Fig. 373 represents the heating apparatus attached to MAUDSLEY'S seed-crushing mills. In this the seed is heated in an iron pan over the open fire with constant agitation. A cast-iron plate, *b*, called the fireplate, rests immediately over the fireplace, and upon this is placed the ring-pan, *c*, also of iron, for containing the seeds, and which is held immovable by the pins or bolts, *a a*. The agitator, *f*, is employed to prevent the scorching of the seeds by continued contact with the iron plate. It is appended by a turning joint to the collar, *j*, which revolves with the shaft, *g*, and slides up and down upon it. The shaft, *g*, is turned by the

action of the bevel-wheel, *i*, upon the bevel-wheel, *h*, at the upper end of the shaft. The lever, *k*, is for raising the agitator; and *e*, a catch for holding it in its

Fig. 373.

place when it has been raised to the proper height. The heated seed is removed from the ring-pan by the funnels, *d d*, into which it is caused to fall by pulling the case, *c*, by means of the handles, *b b*, and the bags are suspended to the funnels by means of hooks, *e*.

If fine cold-drawn oil is required, the seed-flour is subjected at once to pressure, without previously heating; but the method most commonly pursued is that given above. The crushed cake is inclosed in a press-cloth or bag previous to its introduction into the case. The bags and cloths used for this purpose are made of different materials, the object being to have them sufficiently strong to bear the force exerted; while, at the same time, they are not so thick or porous as to retain any great quantity of liquid. Woollen cloth is especially manufactured with a view to its application to this process of expression, and is the material usually employed, either wrapped in horse-hair cloth or otherwise.

Several different kinds of presses are used in the extraction of oil, as the screw-press, the wedge-press, and the hydraulic press. Of these the wedge-press is the most frequently employed. It consists of a large press-box, either hollowed out of a strong block of stone or timber, or otherwise constructed of sufficient strength to bear the enormous pressure of the wedges. The bags of seed are placed between iron plates, which are united at bottom in the form of a book cover. These plates are each provided with three side ribs; the immovable ones press against the sides of the case, and the movable against the intermediate wedges; and they are pierced

with numerous apertures to allow the oil to percolate more easily.

As the product of oil is, to a certain extent, proportional to the intensity of the pressure, it is more economical to employ that kind of apparatus which gives the most power. The use of either vertical or horizontal hydraulic presses is, therefore, to be preferred to the form of press above described. An important improvement in this press, as used for the expression of oil, has been introduced some time ago, and consists in the employment of double-sided presses, and into the division between the two walls steam is introduced. The press thus heated renders more easy the extraction of the oil. Each hydraulic oil press is usually double—that is, it has two vertical rams placed parallel to each other, so that while the pressure is exerted on one side, the other is being emptied of its contents. The first pump has usually about two and a half inches diameter for a ram of ten inches, and the second pump one inch; both are worked by steam-power, and the pressure exerted is from three to four hundred tons. Many advantages, however, are attached to the use of the old form of press; for it is necessary, in order to accomplish the object efficiently, that the press should be capable of maintaining unrelaxed the degree of compression which has been produced at each successive effort, and that it should not allow the particles, by their elastic force, to regain to any extent their original condition. This quality is possessed to a greater extent by the wedge than by the hydraulic press. The former will maintain for an indefinite length of time any degree of compression which may have been applied to the substance placed in it; but not so the latter. The pressure in the hydraulic press is communicated through a liquid, and maintained by the action of valves, and it is found impossible in practice to prevent a slight leakage, which necessarily diminishes or relaxes the force of the pressure when the pump is not in action. It is necessary, therefore, more frequently to renew the force when conducting the process of expression with the hydraulic press, than is the case with the wedge press.

The oil obtained by the first expression is of the finest quality, and is kept apart from that yielded by subsequent processes. After removal of the flattened seed-cakes from the press and bags, they are returned to the millstones, and crushed and finely pulverized. The fine meal thus produced is submitted to a second compression, sometimes with the addition of a little water, and with the assistance of heat. The temperature to which it is raised is about 155°, and it is constantly agitated by a stirrer moved by machinery. The oil resulting from the compression after this process is of the second quality. In some countries, and particularly in Holland, a still further quantity of oil is extracted, otherwise the soft and fat cakes are sold as food for cattle. The last process of extraction is merely a repetition of the second, except that the pulverized cake is kept for some time at the heat of boiling water, and that a greater pressure is applied than before. The oil obtained is of the lowest quality, and the hard and dry oil-cakes cannot be applied otherwise than as manure.

Fig. 374 is a representation of a mill that may be worked by water-power, wind, steam, or other available means, acting directly on the wheel, *W*, which engages with another wheel, *W'*, mounted on the shaft, *s s*. The stamping or crushing of the seeds is effected by the pestles, *c c*, and mortars, *D D*. The framework, *A A*, supporting the pestles, consists of four strong uprights, bolted firmly together by means of the cross pieces, *B B*. The pestles work in notches attached to the rails, for the purpose of guiding their motion. The raising of the pestles is effected by means of wipers, *r r*, attached to the shaft, *s s*, and so arranged that each revolution raises the pestle twice. The wipers consist of a square socket affixed to the shaft, with arms and rollers at their extremities, so as by avoiding friction to confer greater durability upon the apparatus. When not at work, the pestles are raised by levers, so

Fig. 374.

that the lifts are quite clear of the wipers. The press boxes are similarly constructed to the wedge-presses before alluded to. *E E* are the drivers that strike the wedges, *w w*; and the stampers, *F F*, strike the relieving wedges, *i i*, and serve to disconnect the apparatus. These rams are worked by wipers, *r' r'* affixed to the horizontal shaft. The grinding apparatus, shown in the same figure, is also attached to the machine, and is worked by the same motive power. The running granite stones revolve in a powerful frame-work attached to a vertical axis, which also slowly revolves by the action of a cog-wheel at the extremity of the horizontal shaft upon a similar wheel attached to it. A double motion is thus communicated to the stones—one by which they are carried round upon the bed or floor of the mill, and the other on their own axis. The horizontal axis, *A' A'*, passes through the vertical axis; and to give greater freedom of motion, and to allow the stones to pass over any heaps of seed without straining, the hole for the axle is vertically oval, and of sufficient width. The vertical shaft revolves in a brass bush, laid in the centre of a block of wood; and the horizontal shaft passes through to such an extent, that one of the runners is two-thirds of its own thickness nearer the vertical shaft than the other, and the stones are thus caused to pass over a greater extent of surface than they would, were the

vertical shaft equidistant from each. The seed, spread and dispersed by the motion of the stones, is again brought into their path by means of rakes or sweepers attached to the framework, and revolving on the surface of the bedstone. The inner rake collects the seeds under the outer stone in the form of a ridge, over which the stone passes and flattens it, when the outer rake collects it again into a ridge in the line of motion of the inner stone. The outer rake consists of two parts, one of which presses closely on the wooden hoop of the raised border, and pushes the seed obliquely inwards, while the other part gathers up the grain which has spread towards the centre. The inner rake has a joint near the middle of its length, by which the outer half of it can be raised from the nether stone, while the inner half remains in contact with it, and continues to remove the moist paste. When the seed is sufficiently bruised, the outer end of the rake is lowered and gathers up the paste, and carries it obliquely outwards to the raised border, whence, by an open part of the rim, it falls out into troughs placed to receive it. The latter are perforated at bottom, and a quantity of very pure oil oozes out and is conducted to a cistern apart.

A machine for expressing oils was invented by BESSEMER and HEYWOOD of London, and secured by patent, sealed in May, 1849, in which the materials to be operated upon are forced, by means of a plunger or piston, into and through a pervious vessel which, while allowing the oil to percolate, prevents the passage of other matters through its pores. This oil-press is shown in longitudinal section in Fig. 375. The bedplate or framing, *a a*, which should be cast in one piece, forms at *a'* a cistern for the reception of the oily matters as expressed from the seed or other substance, and at the opposite end of this plate there are projections, *a''*, in which brasses, *b*, provided with caps, *c*, are fitted, and form bearings in which the crank-shaft, *d*, revolves. Two other projections, *a'''*, are also cast on to the bedplate, and are provided with caps, *e*, so as to retain the pressing cylinder firmly in its place. The latter must be of sufficient strength and thickness to withstand the amount of internal pressure exerted. The *lining*, fitted within the cylinder, *f*, consists of a tube of gun-metal, having a spiral groove cut on the outside of it, and having the appearance of an ordinary square threaded screw. At very short intervals all along the spiral groove there are conical holes drilled through the tube, *n*, and communicating with the interior of it. At *t t* the inside of the tube is enlarged, and is provided with a steel collar, beyond which the tube is reduced in diameter. A plain cylindrical bag, with open ends formed of fustian, or other similarly pervious material, is made to fit closely to the inside of the tube, *n*, and within this bag is placed a cylinder of wire-gauze, or finely perforated metal. The steel collar, *t*, is forced into the end of the wire-gauze, by which it becomes driven into the narrow part, and is securely held there by the pressure of the collar, *t*. The bag and wire-gauze are then stretched over the end, *n''*, of the tube, and the collar, *u*, driven tightly on, by which means the bag and wire-gauze are securely held in their places.

The lining tube, *n*, is then put into the pressing cylinder as far as the shoulder, *g*. A tubular piece, *h*, is next put in, and brought into contact with the collar, *u*, and then the gland, *i*, is screwed home, whereby the lining, *n*, is firmly retained within the pressing cylinder. The end of the pressing cylinder is contracted at *f'*, and forms a shoulder for the abutment of the collar, *j*, the diameter of the aperture of which regulates the pressure to which the matters are

submitted. Within the tube, *n*, there is fitted a solid plunger, *k*, which receives a motion from the crank, *d*, by means of the connecting-rod, *l*, the parallel motion being obtained by the wheel, *m*, on the cross-head, *o*, traversing on the side of the bedplate. *x* is a hopper bolted to a flange on the pressing cylinder, and in communication with it there is an opening in the tube, *n*, corresponding with the opening into the hopper, so that the substances placed in the hopper

Fig 375.

may drop into the tube, *n*. Where the plunger, *k*, is withdrawn from beneath the opening at that part of the pressing cylinder which is occupied by the lining, there are drilled numerous small holes, *f'''*, communicating at various points with the spiral groove in the tube, *n*. On the outside of the pressing cylinder there are formed two collars, *f'''*, which abut against the projecting pieces, *a''*, and caps, *e*, and cause the pressing cylinder to be retained firmly in its place. When steam is the motive power applied to the oil-press, the crank which is actuated by the steam piston is formed on the end, *d'*, on the crank shaft of the oil-press, and placed at such an angle to the crank, *d*, that when this crank is pushing the plunger, *k*, to the end of its stroke, the steam piston will be at half-stroke, whereby the motive power applied will be greatest at the time that the press offers the greatest resistance; and the steam piston, also, when passing its dead points, will have to overcome the friction of the machinery only, as the plunger, *k*, will be in the middle of its back-stroke. If other motive power than steam is applied to turn the crank, *d*, it is necessary to have a fly wheel on the shaft, *d'*, as also such cog wheels as are necessary to connect it with the first mover.

In applying this apparatus to the expression of oily seeds, the latter, after grinding, and heating if necessary, are introduced into the hopper, and motion being transmitted to the crank in the manner before described, the plunger, *k*, commences a reciprocating movement in the tube, *n*, of the pressing cylinder; each time that it recedes in the direction of the crank, it moves from under the opening in the hopper and allows a portion of the seed to fall into the tube, while the reverse motion of the plunger drives it towards the open end of the cylinder, its passage being much retarded by the friction against the sides of the lining of the tube, but chiefly by the contraction of the escape aperture through the collar, *j*; the plunger, therefore, exerts an amount of pressure upon the seed corresponding to the size of the

escape aperture. The expressed oil, passing through the wire gauze and bag, finds its way through the perforations into the spiral channel, and from thence it finds egress by the perforations, *f'''*, in the pressing cylinder, and as it falls is received by the cistern, *a'*, from which it is drawn by the pipe, *y*. Two or more of these pressing cylinders may be used side by side, actuated either by one crank throw, or by separate throws upon one shaft, placed in such a manner as to equalize as far as possible the amount of resistance throughout the revolution of the crank shaft, and instead of the cylindrical pressing plunger, an angular section may be given to the pressing vessel and plunger. Besides its use in the extraction of oil from seeds, this press may be employed in the expression of other matters containing oil.

In cases where it is necessary to heat the bruised or ground seed during the process of expression, the pressing cylinder is made of larger diameter and of greater length, and the cistern, *a'*, is divided into two separate compartments, over both of which the pressing cylinder is to extend; a strong wrought-iron tube is inserted in its open end, and extends about half-way to the hopper, where it terminates in a solid pointed end. This tube occupies the centre of the pressing cylinder, and in the annular space around it are the ground seeds or other matters to be pressed. The temperature is raised to the required point by steam let into this iron tube, the end of which, extending beyond the cylinder, is securely attached to a bracket projecting from the bedplate, and is thus held firmly in its place, notwithstanding the force exerted against the pointed end. Thus arranged, the ground seed or other matters falling into the pressing cylinder, are thrust forward by the plunger, and give out a portion of oil in that state known as *cold drawn*, and which falls into the first compartment of the cistern, *a'*; the further progress of the meal along the pressing cylinder brings it in contact with the

pointed end of the heated tube, where it divides and passes along the annular space between the tube and the lining, and being thus spread into a thin cylindrical layer around the tube, it rapidly absorbs heat therefrom, and a second portion of oil is given off and received by the second compartment of the cistern, and thus the two operations of hot and cold pressing are carried on collaterally.

BESSEMER and HEYWOOD's patent further includes a method of treating oily and oleaginous substances for the extraction of their oil, in which the matters to be operated upon are subjected to the action of pressure in water, so as, after temporary admixture of the oil with water, to facilitate the separation of the oil from the matters containing them.

The apparatus used is represented in Fig. 376 in vertical section taken through the centre of the apparatus. It consists of a cast-iron cistern, A, having semicircular ends, and open on the upper side; at one end of it is a cylindrical vessel, B, with hemispherical ends. This vessel is of considerable strength, and should be capable of withstanding a pressure of five

Fig. 376.

thousand pounds to the square inch. It is held in an upright position by a flange, c, formed upon it, and extending round one half of its circumference. This flange rests upon a similar one formed around the upper side of the cistern, A, and is bolted thereto. At the upper part of the vessel, B, is formed a sort of basin, b, the edge of which supports an arch-shaped piece of iron, d. At the centre of the basin is an opening into the vessel, and a hydraulic cup leather, e, is secured

within the opening by means of the collar, g; in the bottom of the vessel, B, there is also an opening into which is fitted a cup leather, h, secured in its place by the ring j, which is firmly bolted to the vessel, B. A strong wrought-iron rod, K, extends from the top of the arch, d, down through the vessel, B, having two enlargements or bosses, k, k', formed upon it, which are fitted to the cup leathers. The upper part of the rod, K, has a screw formed upon it at K'', which passes through the boss, k, and enters the boss, n, in which a screw thread is formed. The boss, n, is provided with handles, p, by turning which the rod, K, may be raised or lowered when required. R is a pipe through which water may be injected into the vessel, B, by a force pump, such as is generally employed to work hydraulic presses. S is a cock whereby a portion of the contents of the vessel may be run off, and the pressure relieved when requisite. The two bosses, k and k', being of equal area, whatever pressure may be exerted within the vessel, B, it does not tend to lower or raise the rod, K, but, acting on the cup leathers, preserves the joint tight, and prevents the matters under pressure from leaking out. This form of apparatus is applied principally in the extraction of the portion of oil remaining in the *marc* or cake that has already undergone the first expression. For this purpose the cake is finely ground, and mixed with as much warm water, or water rendered slightly alkaline, as will reduce it to a semi-fluid state. This is then submitted to the action of the apparatus as follows:—The handles, p p, are turned round, and the boss, k, withdrawn from its opening, while the boss, k', which is much longer, still closes the lower aperture. The semi-fluid materials are then put into the basin, b, and fall from thence into the vessel, B, when it is fully charged. The rod is again lowered, and the communication with the hydraulic press pump is made by means of a tap attached to the pump, from which the water flows through the pipe, R, into the vessel, B, and thus, with a few strokes of the pump, the whole of the contents of this vessel will be subjected to the requisite pressure. An interval of a few minutes is allowed for the combination of the oil and water; the cock, s, is then opened, and a small portion of the fluid contents of the vessel allowed to escape into the cistern; the pressure being thus relieved, the handles, p p, are again turned, so as to lift the rod, K, sufficiently high to withdraw the boss, k', from the lower opening. The contents of the vessel, B, then flow out into the cistern, A, and the boss, k', being again lowered so as to close the lower aperture, the vessel may be refilled for another operation. The pressure thus brought upon the mixture of oleaginous matters and water will cause the oil therein contained to mix with the water, and the former may be afterwards separated from the milky-looking fluid, either by repose in suitable vessels, or by evaporation of the water by heat. If the oil is required for soap-making, the mixture of it with the water may be applied without separation. After the materials have been withdrawn from the cistern, A, and strained, the solid portions are again submitted to pressure, and from the expressed liquid the albumen is removed by boiling, and the oil separated as before.

H. W. WOOD, of London, some years ago invented a process for the extraction of certain oils from seeds, in which diluted acid is applied to the seed, previous to pressure; whereby, according to the patentee, the seed will part more thoroughly with the oil. The process is as follows:—During the grinding of the seed, it is regularly sprinkled with the dilute acid, in the proportion of two ounces of hydrochloric acid, of specific gravity 1.160, mixed with six and a quarter pounds of water to every hundred pounds of seed. The mixture of seed, acid, and water is permitted to stand for a longer or shorter period, depending on the quality of the seeds, usually not more than twelve hours. The mixture is then submitted to pressure in bags, the latter being placed alternately in the press with plates of iron. A hydraulic press is preferred. By this treatment, a more than ordinary quantity of oil is said to be obtained from a given weight of seed.

Amongst the great number of oils now known, there are several which are admirably suited for various purposes, but which nevertheless, on account of their price, depending usually on local circumstances, such as cost of freight, *et cetera*, are very little or not at all used by our manufacturers. Should, however, accidental circumstances at any time occasion an advance in the price of the more common oils, some of those above alluded to might be procured in large quantities, and would probably, in a short time, altogether supersede many of the oils now in use. Whilst, therefore, it is desirable to draw the attention of manufacturers and consumers to the numerous foreign and colonial oils not at present well known in this country, it is, at the same time, important to point out how greatly the value of such oils depends on the care bestowed on their preparation, especially as regards cleanness of the seeds, and the careful exclusion of impurity of all sorts in the process of extracting the oil.

PURIFICATION OF SEED OILS.—Many oils in their natural state are always more or less impure, and some of them so viscous as to be quite inapplicable to the lubrication of machinery, or to illuminating purposes, without previous purification. The impurities consist for the most part of albuminous, mucous, gelatinous, and coloring matters. A great part of the mucilaginous matters, and all bodies merely in a state of suspension, are deposited by repose for a sufficient length of time; but in order completely to clarify the oil, it is necessary to employ other means of depuration. The method most generally adopted is that suggested by THENARD. As already noticed, the concentrated acids exert a remarkably energetic action upon the combustible oils; if the power of these acids, however, is weakened by lessening the quantity used, the foreign matters in admixture are then chiefly affected. Sulphuric acid, for example, in the proportion of one or two per cent. of the oil, acts as a depurating agent, precipitating the mucilage and parenchymatous matters; first, by its powerful dehydrating action, it removes the water, by which these substances were held in solution in the oil, and afterwards chars the mucous matters themselves, thus either rendering them insoluble, or otherwise effecting their destruction. The oil itself is also to a certain extent acted upon: it

becomes green or dark brown, and after some time yields a deposit of the same color, becoming itself perfectly bright and clear. THENARD's purifying process is conducted as follows:—The oil, first heated to 100° or upwards, is placed in a convenient vessel, and from one to two per cent. of sulphuric acid is gradually poured in, with constant and violent agitation. As the action of the acid depends more or less upon the amount of contact between the two liquids, as well as upon the degree of heat, it is, of course, desirable to employ such an apparatus as will allow the easy and rapid admixture of the oil and acid. This is best supplied by an agitating tub, movable round its own axis, or it may be itself immovable, but with a movable fan in its axis. When, after continued agitation, the dark-colored fluid appears to consist of a clear liquid, holding flocculent matter in suspension, the action of the acid is terminated. This, however, is perceptible only after about twenty-four hours' repose. At the end of this period, a quantity of water, heated to 140°, and equal to about two-thirds of the oil, is added, and the mixture is agitated until it acquires a milky appearance. After several days' repose, the clarified oil rises to the surface of the mixture of acid and water, and the black flocculent matter forms a deposit beneath the two liquids. The oil, however carefully it may be decanted, always requires to be filtered to remove the matters still held in suspension. To effect this operation, the oil is drawn at once from the depositing tubs into vats with conical openings in the bottom stopped with cotton plugs, or it is passed through baskets lined with moss or carded cotton. The filtration is always a difficult operation, the plug-holes becoming quickly and repeatedly choked with the solid matters. A much better method is to pass the oil through a displacing funnel, the apertures in the diaphragm of which are furnished with filaments of carded wool or cotton. By some manufacturers a modification of THENARD's process is pursued, which consists in neutralizing the sulphuric acid by the addition of a mixture of chalk and water, or milk of lime. The operation is then concluded in a much shorter period, and the separation of the oil and water is far more complete.

The black deposit produced by the action of sulphuric acid, after having been heated and subjected to pressure, yields about eighty per cent. of oil, which, after clarification and filtration, is little inferior to the oil first obtained.

COGAN's modification of THENARD's method of purification is designed to obviate the difficulty of getting rid of the charred matter and excess of acid employed. Steam is the agent made use of; and by its judicious introduction the oil appears to be almost entirely freed from acid, and the black feculent dregs subside in the course of twelve hours, leaving the supernatant oil quite clear and greatly improved in color, and in those qualities for which it is valued by the painter. The two combined processes are conducted as follows:—The quantity of oil operated upon is about one hundred gallons. For this about ten pounds of sulphuric acid are required, and this is diluted with an equal bulk of water. To the oil, placed in a convenient vessel, one-third part of the dilute acid is added, and

the whole is carefully stirred for an hour or more with a wooden scoop, till the acid is thoroughly incorporated with the oil, and the latter has assumed a darker color. A second similar quantity of acid is then added and mixed with agitation as before, and after this, the remaining third of acid is poured in. The stirring is now continued incessantly for two hours more, when the color of the mixture resembles that of tar. It is allowed to stand at rest for twelve hours, and then transferred to a copper boiler. This latter has a steam pipe entering at the bottom, which divides into three or four branches, each terminating in a perforated plate. Steam is forced through this pipe, and, passing in a very divided state into the oil, penetrates into every part of it, and raises the temperature to 212°. The steaming process is continued for about six hours, at the end of which time the oil is transferred to a cooler, of the shape of an inverted cone, terminating in a short pipe, provided with a stopcock inserted in its side a few inches from the bottom. After standing twelve hours, the black watery acid liquor is withdrawn by opening the stopcock at the bottom. The clear and limpid oil is then drawn off by opening the tap in the side of the cooler. What remains below this cock is turbid, and this, being let out into a reservoir, is either clarified by subsidence, or mixed with the next portion of raw oil.

The quality of oils to be used for the lubrication of machinery, or for illuminating purposes, is much improved by the application of solution of tannin, by which the foreign matters are rendered more completely insoluble. In this process a strong infusion of nutgalls is mixed with the oil by agitation. After deposition the clear oil is decanted from the precipitate, and similarly treated with a solution of acetate of lead, acetate of alumina, or sulphate of zinc, to remove any excess of tannin. During these operations, the oil should be kept as near 70° as possible. The oil is afterwards dried by agitation with freshly-calcined sulphate of lime, or anhydrous carbonate of soda, which are allowed to deposit by rest. The addition of from five to ten per cent. of essential oil, or of a hydrocarbon—as mineral naphtha or oil of turpentine—to oils purified as above, renders them much more valuable as sources of light. They are intimately mixed either by agitation, or by passing the hydrocarbon in the state of vapor into the oil.

The treatment of oils and fatty matters, by submitting them to the action of streams of air or steam, is an efficient method of purification and bleaching. This mode of treatment was adopted by T. J. KNOWLYS of Lancaster, who, some years ago, obtained a patent for a process for clarifying and improving the quality of linseed and other oils to be applied in the manufacture of paints, varnishes, *et cetera*, by exposing the oil to the conjoint action of light and air. To this end the oil is first heated in the usual manner, or mixed with a portion of manganese or litharge, which are left to react upon it for a few days, and then separated by straining. The filtered oil is then exposed to the action of light and air, or steam, in a suitable vessel, and with constant agitation, so as to present continually a fresh surface.

OLIVE OIL.—*Huile d'olives*, French; *olivenöl*, *baumöl*, German; *oleum olivæ*, Latin.—Olive oil appears to have been known from the remotest antiquity. The olive tree—*olea europæa*—is one of the prettiest in nature. Very few vegetables have been so repeatedly noticed or so enthusiastically described by the ancient writers, and from the earliest ages it has been adopted as the emblem of benignity and peace.

The precise period of the discovery of olive oil, and of its application to the wants of man, is not recorded. It appears to have been known from the earliest times, since the method of producing it is mentioned by Moses, and what is very remarkable, it is, with slight variation, the process employed at the present day. It is obtained from the bluish or brownish green integument, or sarcocarp, of the fruit or olives. Several varieties of olives are met with in commerce, but the most common is the small French *olea europæa longifolia*, and the large Spanish *olea europæa latifolia*. The ingathering is performed in different ways, according to the kind of oil to be extracted. If the olives are gathered some time before they are ripe, they yield an oil with an acrid and bitter taste. When more ripe, but still before they arrive at maturity, the oil possesses the peculiar taste of the fruit, and may be preserved for a lengthened period without becoming rancid. When fully ripened, so as to drop from the trees, they yield a fine oil, but more fatty, and also more susceptible of change by exposure. November and December are the principal harvest months, and if allowed to remain longer on the trees, the olive gradually deteriorates, and yields an oil of very inferior quality. To obtain the finest oil, the olives should be gathered by hand, for if bruised, as in the usual method of beating the fruit from the trees with poles, unless used directly, they ferment, and the oil acquires a highly disagreeable odor and taste.

The process for procuring olive oil is somewhat modified in different countries, though the principle is the same in all, namely, for the purest, gentle pressure of the freshly gathered fruit in the cold; for common or second oil, stronger pressure, aided by partial fermentation of the olives, and the heat of boiling water; and for another still inferior kind, by boiling the husk or *marc*, after the preceding treatment, with water, when a mucilaginous oil rises and floats on the surface. All the varieties are left to repose for a month after being extracted, in order that the impurities may subside.

The following is the method pursued in the South of France:—The ripe olives are crushed in a mill of the most rude construction, comprising usually a single millstone turning in a circular bed; sometimes two millstones, placed wide enough apart not to crush the seeds. The workmen remove all the pulp when sufficiently crushed, and place it in rush sacks, which are heaped up, to the number of eighteen or twenty, on the platform of a press. This is also of a very rude description, and is only capable of a very slow and feeble pressure. The oil which first exudes from the bags, when the olives are of good quality, and the pressure is nicely regulated, is the variety known as salad oil, and is much in request for the supply of the table. After the first pres-

sure, the pulp still contains a considerable quantity of oil, so mixed with albuminous matters that it cannot flow out. To extract a portion of this oil, the press is taken apart, the cakes are broken up in the bags, and the nearly dry residue is digested with boiling water, and again pressed as before. The boiling water being absorbed causes the pulp to swell; the albumen coagulates, and the more fluid oil runs out freely. This operation is repeated two or three times. For the reception of the water containing the oil, two tanks are used, so arranged that in the one the liquids separate into two layers, whilst the other is filling. The upper layer, consisting of oil, is ladled off, and the water below, which still contains oil in suspension with mucus, is collected for further separation into a narrow and deep cistern, from which the water can be removed by a long siphon. After deposition of a portion of water, it is drawn from underneath, the cistern is again filled with a further quantity of the mixture, and when a sufficient quantity of oil swims on the surface, it is skimmed off, as oil of inferior quality. Owing to the imperfections of these processes, a quantity of oil still remains in the refuse in the bags, and the producers of oil find it worth while to submit it to a third operation. The large amount of time and labor consumed in the complete exhaustion, and the fact that the oil obtained is not of as good quality as it might be, has induced DUMAS to give his attention to this subject, and he has suggested several improvements in the old method of extraction. This eminent authority recommends, for the crushing of the olives, the use of mills of similar construction to those employed in the extraction of oil from seeds; and instead of the common presses, he proposes the employment of horizontal hydraulic presses, or of the wedge presses used to remove the oil from crushed seeds, by means of which the oil would be withdrawn more easily and rapidly, and the exhaustion would be much more complete.

The last operation, in the method usually employed, is as follows:—The cake or *marc*, after the second pressure, is immediately moistened with water, as a preventive of fermentation, which otherwise quickly ensues, and effects the destruction of the last traces of oil. The absorption of water is accelerated by heaping the moistened cake in layers in vats. The next step is the separation of the stones: this is effected by means of two machines, adjoining each other, and worked by the same motive power. The first consists of a vertical millstone turning in a pit of masonry or woodwork, through which flows a current of cold water. The cake passed through this is conveyed through a trap-door into the other machine of similar construction to the first, except that the crusher is heavier; and there is attached to the axle an arm, which serves to agitate the paste with the water. In this process the broken stones fall to the bottom, whilst the lighter parts, with the kernels of the seeds, rise to the surface, and are removed by means of hair sieves. These unctuous matters are dried over a fire, until they form a stiff paste, which is then submitted to pressure as before. The oil thus obtained is applied to lighting purposes, and in the manufacture of soap. By the adoption of

the improvements suggested by DUMAS, he considers that this last very tedious course of operations might be entirely dispensed with, and still the same quantity of oil would be obtained, and that of superior quality. Another very desirable improvement would be effected if the growers themselves would extract the oil, instead of, as is usually the case, sending the fruit to the common miller. At these mills they are often allowed to remain in heaps for some days, or until the mill is at liberty; from which cause the oil is of far inferior quality than would otherwise be obtained.

In Naples, the machinery employed by the peasants in the preparation of Gallipoli oil is of the rudest kind. The olives, when ripe, are allowed to drop from the trees, and are collected and conveyed to the mill, chiefly by women and children. The oil, when expressed, is inclosed in sheep or goat skins, and carried on mules to Gallipoli, where it is allowed to clarify in reservoirs cut in the rock on which the town is built, and its ultimate value depends, in a great measure, on the nature of this cistern. In point of fact, Gallipoli owes its celebrity to the facility of the formation of these cisterns, as in them the oil soon clarifies, and may be preserved for a lengthened period without becoming rancid.

The finest olive oil is of a pale yellow color, sometimes inclined to green. It has scarcely any smell, but a bland, mild, and agreeable taste; occasionally it has a nutty flavor, and when swallowed, leaves a slight sense of acrimony in the throat. It is insoluble in water, slightly soluble in alcohol, and in one and a half times its weight of ether. Its specific gravity is 0.910 at 60°. At 36° it deposits white granules, especially if heat has been applied in its extraction. At 22° it deposits twenty-eight per cent. of its weight of margarin, fusible again at 68°, and it yields also seventy-two per cent. of olein. Of the different kinds of olive oil met with in commerce, the produce of Aix, known as Provence oil, is the most esteemed. Florence oil, imported from Leghorn in flasks, packed in chests containing thirty of these, is a very fine kind, used for culinary purposes. Lucca oil is imported in jars holding nineteen gallons each. Gallipoli forms the largest proportion of that brought into this country, and is imported in casks. Puglia and Calabria are the provinces of Naples most celebrated for its production. Sicily oil is principally produced at Milazzo, and is of inferior quality. In some countries, and especially on the continent of Europe, olive oil constitutes an important article of diet. It is extensively used in England in the manufactures, and especially in the treatment of woollen cloths. The inferior kinds are much used in the production of soaps, particularly of the varieties known as Marseilles and Castile soaps. Being less liable to become thick and viscid by exposure to air, it is often used for oiling delicate machinery. For application to watch and clock work, the oil is refined by cooling, separating the fluid portion, immersing in it a slip of sheet lead, or some shot, and exposing it to direct sunlight in a corked phial, when a whitish matter gradually subsides, and the oil is rendered clear and colorless. This, when decanted, is fit for use.

PETER BANCROFT, of Liverpool, in 1846, patented a

process for purifying olive oil, which consists in treating the oil, heated to about 90°, with a strong solution of potassa or soda, either as carbonate or in the caustic condition, giving preference to the latter, as it operates more quickly. The specific gravity of the solution may be 1.2 or even stronger. The oil is kept constantly agitated during the addition of the alkali, and the operation is at an end when a small portion of the oil, placed in a glass bottle, and shaken with a further addition of solution of alkali, deposits only a clear liquid, free from soapy matters. The quantity of solution of alkali required varies from three and a half to eight per cent. The oil is decanted after deposition of the soapy matters, and passed through a filter. So treated, this oil is said to be very valuable as a lubricant for machinery.

Adulterations.—The superiority of olive over other kinds of oil, and its higher price, render it liable to adulteration with rape and poppy oils, and especially with lard oil—what is called *superfine* Lucca oil often containing as much as sixty or seventy per cent. of the latter. Several methods have been proposed to detect these sophistications. Poppy oil may be discovered by the phenomena of *beading*, or the appearance of a number of air bubbles on the surface after violent agitation of the oil, which are not produced with pure oil. GURBOURT recommended congelation, but this test is ineffective unless the adulterant is present in large quantity. The most reliable test is that suggested by POUTET, which depends upon the peculiar action of nitrous acid upon olive oil. A nitrate of mercury is prepared by dissolving six parts of quicksilver in seven and a half parts of nitric acid, of specific gravity 1.36, without applying heat. When one part of this freshly prepared solution is added to ten parts of pure olive oil, the mixture becomes concrete in the course of a few hours. The admixture of foreign oils prevents this congelation, so that the resulting mixture is more or less liquid in proportion to the quantity of the adulterant present. The twentieth part of poppy oil is easily detected by this method, but, in order to arrive at satisfactory results, a comparative experiment should be made with a mixture of oils of known composition. Other methods will be given when treating generally of the adulteration of oils and fats.

Physiological Effects.—According to Dr. BEAUMONT, olive oil is extremely nutritious, but rather difficult of digestion. However, when taken as a condiment with salad, it promotes the digestibility of the latter. In larger doses, olive oil acts as a gentle laxative, with freedom from pain. It is often administered in cases of irritant poisoning, as an emollient and demulcent, to shield the stomach from the action of acid and corrosive substances.

Statistics.—The quantity of olive oil imported annually, from the years 1844 to 1850 inclusive, was as follows:—

	Gallons.
1844.....	3,770,424
1845.....	3,103,380
1846.....	2,150,568
1847.....	2,190,384
1848.....	2,541,672
1849.....	4,274,928
1850.....	5,237,316

ALMOND OIL.—*Huile d'amandes*, French; *mandelöl*, German; *oleum amygdalæ*, Latin. This oil is obtained by expression from the seeds of the *amygdalus communis*, either sweet or bitter, usually from the latter, on account of their comparative cheapness, as well as of the greater value of the *marc* or pressed cake. Almonds were well known to the ancients, and are alluded to in the writings of MOSES—Genesis xliii. 11. HIPPOCRATES employed the expressed oil, as well as the almonds themselves, both sweet and bitter, in medicine. DIOSCORIDES describes the method of extracting the oil.

ROBIQUET discovered in bitter almonds from one to 2.5 per cent. of a peculiar principle not contained in the sweet variety. This principle, which is termed amygdalin, is a colorless, crystalline, nitrogenous body, with a bitter taste, and free from odor.

The fixed oil of almonds is obtained by expression from either kind; and if contact of water be carefully avoided, the oil from the bitter is quite as bland as that from the sweet variety. The almonds, previously cleansed of the adherent furz and dust by being well shaken and sifted, are bruised or coarsely powdered, and pressed in hempen cloths or bags, between iron plates, either cold, or, preferably, slightly and uniformly heated by hot water or steam. The yield of oil varies from twenty-eight to fifty-four per cent. When recently expressed, this oil is turbid, but by rest and subsidence becomes quite transparent. The mucilaginous matter should, however, be separated as quickly as possible, as it promotes rancidity; and the oil should be preserved in well-stopped bottles.

Almond oil is pale yellow and very fluid, inodorous when fresh, and of a faint oleaginous taste. It quickly becomes colorless by exposure to light. It remains fluid at a much lower temperature than olive oil, but at 14° it deposits twenty-four per cent. of concrete matter. Its specific gravity at 60° is about 0.918. Cold alcohol takes up about a twenty-fourth of its weight, and boiling alcohol a sixth. It is also very soluble in ether. Its principal use is in pharmacy, as an ingredient in emulsions, and occasionally in liniments, ointments, and soaps. As it contains less margarin than olive, it yields softer soap, and is better adapted to the preparation of oleic acid. The cake left after expression of the oil is sometimes ground, and is known as almond powder, and used as a detergent for preserving the skin soft and pliable.

Adulterations.—Commercial almond oil is frequently adulterated to a considerable extent with lard or olive oil; indeed, according to MORFIT, what is sold as the genuine article is often olive oil, merely flavored with that of almonds. According to PEREIRA, teal oil, or oil of *sesamum*, is occasionally substituted for almond oil, from which, however, it may be known by the deposit of margarin being formed much more readily than in oil of almonds.

Physiological Effects.—Almond, like olive oil, is highly nutritive, but difficult of digestion. It possesses also the medicinal as well as dietetical qualities of olive oil. In large doses it is a mild laxative. Its local action is emollient. It is employed medicinally for the same purposes as that of olive. Sometimes it is

administered to allay cough, or as a laxative, but, according to CHRISTISON, is not well adapted for either purpose. It is also used for outward friction, and for cosmetic soaps.

RAPE OIL.—This oil is prepared from the seeds of several species of the genus *brassica*, belonging to the family of *crucifera*, as the *brassica napus*, or winter rape, and the summer rape, or *brassica præcox*. Besides oil and woody fibre, these seeds contain a considerable quantity of mucus, albumen, and other allied substances. Only the driest possible seeds, such as have been stored for several months, and protected from moisture, are expressed. It is usual also to submit the seed to steam heat previous to pressure, as, if the albumen present is not completely coagulated the oil obtained is much less in quantity, and far inferior in quality, to that otherwise extracted. The very large proportion of fluid contents, other than oil, contained in fresh seed, constitutes the great difficulty in obtaining an average oil both as to quantity and quality; but by the above method of treatment this obstacle is overcome, and the oil expressed, containing only a trace of albumen, and a greatly-reduced proportion of mucus, becomes comparatively easy of purification. As newly expressed, even with every precaution, it is viscid, owing to the mucus and other foreign matters unavoidably present. These, and the coloring matter also retained by the oil, lessen its combustibility, and occasion much smoke during its burning.

Purification.—Rape oil is most conveniently depurated by the process recommended by THENARD, and already described. A two-hundredth part of sulphuric acid is added, and the mixture well agitated; it is then left at rest for about twenty-four hours, and afterwards shaken with two-thirds of its bulk of water at 160°. The emulsion thus produced, after standing about eight or ten days in a situation the temperature of which is maintained at 80°, separates into two portions, when the upper layer of clarified oil may be drawn off and filtered through a displacing funnel, the apertures in the diaphragm of which are furnished with filaments of carded wool or cotton, and is then fit for use. In this operation the coloring matter is deposited in the form of dark greenish flocculi, which, by the action of the sulphuric acid, are converted into an insoluble state.

Another mode of treating the several varieties of rape oil has been recommended by DEUTSCH, by which it is said to be rendered more applicable to the several manufacturing and other operations in which it is employed. His process is as follows:—The oil is placed in a copper pan or boiler, and fire-heat applied until the oil begins to be decomposed, when the heat is so regulated as to keep the oil in a uniform state of ebullition for about three or four hours. The spongy scum which separates, after a time begins to subside, whilst the oil becomes clear and transparent, and of a green color. The fire is then removed, and the oil is allowed to settle for one or two days, when the clear green oil is drawn off. If the oil has not acquired a green color, it is an indication that the process has not been well performed, or that the oil employed was of inferior quality. The several varieties of rape oil, after this treatment, may be advantageously employed

for the oiling of wool in the process of its manufacture, and they may also be employed for the lubrication of machinery. For the latter purpose, if it be desired to diminish its fluidity, a solution of caoutchouc obtained by boiling the latter in the oil, may be added to the oil, which should be heated and well stirred, to effect a uniform mixture. The oil may be rendered less fluid by mixing it with tallow or other grease.

WARBURTON'S method of effecting the purification of rape oil is by treatment with caustic alkali, in which the albuminous and other impurities are soluble, and are separated, associated with soapy matters. In a suitable vessel, containing fifty-two parts of caustic soda solution, of specific gravity 1.010, are to be put one hundred pounds of the refined oil; these are to be stirred with a wooden ladle till well mixed. The mixture is then allowed to stand twenty-four hours undisturbed, in a cold place, after which it is then slowly warmed, and again well stirred. After twenty-four hours' subsidence all the oil will have separated; if such should not be entirely the case, the complete separation may be effected by the addition of a small quantity of spirit of wine. The oil drawn off from the liquor is afterwards well washed with hot water, till the pure oil is obtained without taste or color, and if desired, may be passed through a filter. The soap which deposits may be used as an ordinary detergent.

Rape oil is of a light-yellow color and has a peculiar taste and smell. The smell becomes much stronger when the oil is heated; and the color darkens to greenish-yellow when the temperature is increased to 398°. The specific gravity of that from the *brassica napus* is 0.9128 at 60°, and from the *brassica rapa*, 0.9167. It contains forty-six per cent. of solid fat, which congeals at about 28°, but requires to be heated to about 43° before it again fuses. It is employed in the manufacture of woollen goods; in the preparation of some kinds of leather; for oiling machinery; in the production of soap; and also for burning. After purification from mucilage, *et cetera*, rape oil is said to be better suited for the lubrication of machinery than any other oil. It is now extensively used for locomotives, for marine engines, and also as lamp oil. According to Mr. BROTHERTON, a manufacturer of oils, good English-grown rape seed yields oil of superior quality to any foreign seed ever brought to his notice, and he consequently recommends its cultivation to agriculturists. The inferiority of the oil obtained from Indian or colonial seed probably depends, in a great measure, on the want of sufficient care being paid to the purity and cleanness of the seed itself, and not to any real deficiency in the oil.

Colza oil is extracted in the same manner as the preceding from another variety of seed of the same genus of plants—the *brassica campestris oleifera*. It is produced in France in large quantity, and is used for the same purpose as rape oil. It is of a yellow color, and nearly free from odor. Its specific gravity is 0.9136 at 60°. It congeals at about 22°. It is sparingly soluble in cold alcohol, but readily soluble in this fluid when assisted by heat. Colza oil is largely used for illuminating purposes, and may be burned without previous purification.

A Parisian, named NUERBERGER, in 1856, obtained a patent for the extraction of oil from the seeds of other genera of the order *crucifera*. This oil forms a substitute for colza oil, and may be used for lighting and other purposes. The three genera from which the oil may be procured, are the genus *thlaspi*, or shepherd's-purse; the genus *capsella*, or common shepherd's-purse; and the genus *iberis*, or candy tuft. The species *capsella bursa pastoris* yields the largest proportion of oil. The latter is obtained precisely as colza oil, and is also purified in the same manner.

Teel Oil, or Oil of Sesamum.—The plant yielding this oil, the *sesamum orientale*, is extensively cultivated throughout India for the sake of the fine oil expressed from its seeds. The latter are imported from Calcutta under the name of teal seeds. They are about the size of white mustard seeds. Three varieties are known—namely, the white, the colored, and the black. It is principally from the latter that the sesamum oil of commerce is obtained. The seed contains about forty-five per cent. of oil. This has been already mentioned as an adulterant of almond oil, and, according to PEREIRA, may be used as a substitute for the latter.

Oil of Behen or Ben.—This oil is obtained by expression from the decorticated seeds of the *mohringa aptera et oleifera*, a tree resembling a willow, and indigenous to Arabia and Syria, but cultivated also in the West Indies. The oil is colorless and inodorous, and has an agreeable flavor. By repose it separates into two portions, one thick and the other fluid at very low temperatures. The latter, as it resists the rancidifying action of the air, is highly valued for lubricating watch and clock work. The oil itself is much esteemed as an agent for the extraction of the delicate perfume of certain flowers by the process of maceration. It is also used as the base of macassar oil. Oil of ben contains a peculiar fat, named moringin, which, by saponification and decomposition of the soap, yields moringic acid. This acid is solid at 32°.

Beech Oil.—This oil is obtained from the nut of the *agus sylvatica*, or beech-tree. It is extracted either by cold or hot expression of the nut, previously decorticated. The per centage yield is about sixteen. The oil is of a clear, yellow color, is inodorous, but has a slightly acid taste, which, however, is dissipated by keeping or by ebullition with water. Its specific gravity is 0.9225 at 60°. At 29° it becomes solid. It is not well known in this country. In some districts of France, however, it is extensively used for culinary purposes, as well as for the production of soap and as a source of light. The cake remaining after expression of the bruised nut is useful as food for cattle.

Oil of Mustard.—This oil is procured by expression of the bruised seeds of the black or white mustard. The mustard plant—*sinapis*—of which there are several species, appears to be indigenous to this country. It was formerly cultivated in Durham, but is now grown principally in the neighborhood of York. In India and the East, mustard is cultivated solely for the sake of the fixed oil it contains. The seeds of black mustard were first analysed by THIBIERGE, and have been since examined among others by PELOUZE, ROBIQUET,

BUSSY, and FREMY. From their labors we learn that this seed contains myronate of potassa, myrosin, fatty, gummy, and coloring matters, a peculiar green matter, sugar, sinapisin, free acid, and salts. The proportion of oil is about twenty-eight per cent. of the seeds. According to the analysis of JOHN, white mustard seeds consist of an acrid volatile oil, yellow fat oil, brown resin, gum, extractive ligneous fibre, albumen, free phosphoric acid, and salts. ROBIQUET and BOUTRON, however, have proved that white mustard does not contain volatile oil, nor any substance capable of producing it. The yield of oil from white mustard seed is about thirty-six per cent. Oil of mustard is of a reddish or brownish yellow color, and is nearly inodorous. It has a thick oily consistence, and may be preserved for a lengthened period without becoming rancid. Its specific gravity is about 0.916. It requires one thousand parts of alcohol at 0.90 for solution, but dissolves in four parts of ether. By saponification glycerin is eliminated, and by decomposition of the soap produced, *erucic acid* is liberated. The formula for this acid is $C_{44}H_{41}O_3$, HO. It forms acicular crystals which fuse at 93°. Oil of mustard may be applied to the same purposes as rape oil; it has been used in the manufacture of soap, and also medicinally as a purgative and anthelmintic. The expressed mustard cake, owing to its acidity, is unfit for food for cattle, and is only useful as a manure.

Cocoa-Nut Oil is extracted from the kernels of the cocoa-palm—*cocos nucifera et butyracea*—either by expression or by ebullition with water. The cocoa-palm is a native of tropical countries, but does not thrive except near the coast. Five varieties are indigenous to Ceylon. The bark yields a peculiar oil used by the Cingalese in the form of ointment in cutaneous diseases. The nucleus or kernel of the cocoa-nut has been analysed by BRANDES, BUCHNER, and BIZIO, and according to the latter authority is composed as follows:—

	Centesimally
Oil,.....	71.488
Zymome,.....	7.665
Mucilage,.....	3.588
Crystallizable glycerin,.....	1.595
Yellow coloring matter,.....	0.325
Ligneous fibre,.....	14.950
Loss,.....	0.389

Albumen of cocoa-nut,100.000

In Malabar and Ceylon two methods of extracting the oil or *cocoa butter* are practised; the one is by pressure, the other by boiling the bruised nut, and skimming off the oil as it rises to the surface. The kernels of this palm are also brought to Europe, and the oil is extracted by the aid of heat, the fruit having been previously ground or cut into small pieces. The oil, as shown by TINDALL, consists of a fluid and a solid fat, which are most probably distinct and separate in the seeds, but become mixed under the press, and so much the more the higher the temperature is raised; so that fluid or solid fat, or such as is of medium consistence, may be obtained as desired, and according to the amount of pressure applied, and the temperature at which the operation is conducted. Commercial cocoa-nut oil is concrete at temperatures

below 69°, and at about 74° is fluid. The solid constituent of this oil varies from that of other oils, and is named cocostearin or cocosin. The principal use of cocoa-nut oil is in the manufacture of soap and candles. As a material for the production of soap, it is in many respects valuable, the soap being brilliant white, very hard and light, and to a larger extent soluble in saline and alkaline waters than most other soaps, and consequently useful for washing in salt water. Cocoa-nut oil has also been used as a therapeutic agent, and by some is considered little inferior to olive oil. On the continent of India, as well as in Ceylon, it is used as a pomatum for promoting the growth of, and preserving and softening the hair. It is stated also, that if it were perfumed, and used for this purpose by Europeans, its virtues would be displayed to such advantage as to insure its general use. Its odor, and the rapidity with which it becomes rancid, are, however, a great objection to its employment, either in medicine or as a pomatum. The olein of cocoa-nut oil, which remains liquid at ordinary temperatures, cannot be burned in an argand lamp of ordinary construction, in consequence of its charring the wick: with a view to cheapness, and to combustion in what is known as the solar lamps, it may be employed in admixture with spermaceti oil, but the latter is deteriorated in proportion to such addition. Cocoa-nut oil is a very complex fat, yielding, according to GEORGEY, no fewer than six acids on saponification. These acids are—

Caproic acid,	C ₁₂	H ₂₄	O ₂	HO
Caprylic acid,	C ₁₆	H ₃₂	O ₂	HO
Rutic acid,	C ₂₀	H ₄₀	O ₂	HO
Laurostearic acid,	C ₂₄	H ₄₈	O ₂	HO
Myristic acid,	C ₂₈	H ₅₆	O ₂	HO
Palmitic acid,	C ₃₂	H ₆₄	O ₂	HO

Cocosin or cocostearin is separated from the liquid portion of cocoa-nut oil by pressure, by ether, or by solution in boiling alcohol, from which the stearin crystallizes on cooling, exactly as in the case of ordinary stearin. Full information on this, and the acid prepared from it, will be found at page 410, vol. i.

Palm Oil.—This very important fatty oil is procured from the fruit of a species of palm—*avouira elais* or *elais guineensis*—cultivated on the west coast of Africa, and in tropical America. The fruit of the palm is about the size of a pigeon's egg, and of a deep orange yellow color. It consists of a hard stone, within which is the seed, and surrounding the nut is a fibrous, oily, yellow sarcocarp, or fleshy integument, from which, by boiling in water, the oil is separated, rises to the surface, and may easily be collected. Fresh palm oil has an orange-yellow tint, a sweetish taste, and possesses an odor somewhat resembling that of violets ororris root. It has the consistency of butter or lard, is lighter than water, and, by exposure to the air, quickly becomes rancid, and of a paler hue. Its melting point is variable, ranging from 76° to 95°, and is still further heightened by age. It is slightly soluble in cold, more readily in boiling alcohol, but is deposited from the latter on cooling. In ether, it dissolves in all proportions. Palm oil was once considered of no importance in the arts and manufactures. At the present time it is exported from one port on the

African coast to the amount of upwards of twenty thousand tons annually, in exchange for foreign produce; and the annual consumption of palm oil in this country is upwards of twenty-five thousand tons, which are imported in exchange for goods of British manufacture. As it occurs in commerce, palm oil is in a state of rancidity, containing fatty acids in their free state, instead of in combination with oxide of glyceryl. The characteristic orange color of this oil is to be attributed to the spontaneous decomposition of a peculiar principle of the palm, always associated with the oil. The various processes for the destruction of this principle have been referred to in the article CANDLE, and will be alluded to also in connection with the manufacture of soap. Palm oil is composed, according to STENHOUSE and FRÉMY, of margarin, olein, a peculiar fat named *palmitin*, and coloring matter. In addition to these, there are found in commercial palm oil, oleic, palmitic, and sebacic acids in the free state, and also free glycerin. The principal use of palm oil is, after admixture with other oils, in the production of soap and candles. In soap-making, the oil is used both bleached and as imported, according to the kind of soap required; in the candle manufacture, the solid constituent only is used, and is hardened by the addition of wax. In Africa, palm oil is employed by the natives as a kind of butter. In this country, it is occasionally used by way of friction in cases of bruises and sprains.

Palmitin.—This solid fat constitutes about two-thirds of the weight of palm oil. It may be obtained tolerably pure and in large quantities, by pressing palm oil at a temperature of from 50° to 54°, and repeating the operation at about 75°. As thus procured, it appears as a wax-like mass, and is used in the manufacture of a variety of stearin candles, whilst the yellow fluid oil is saponified. It is obtained pure by washing the residue of the second pressure with hot alcohol, dissolving it in hot ether, and crystallizing repeatedly till the melting point becomes constant. Palmitin is insoluble in water, and only very sparingly soluble in boiling absolute alcohol, but very readily dissolves in ether. It fuses at 118°, and congeals on cooling into a friable mass similar to wax. Besides palm oil, palmitin is contained in bees-wax, in cocoa nut oil, and, according to HEINTZ, also in human fat. STENHOUSE represents palmitin by the formula, C₃₅H₇₀O₂, and as being composed of palmitic acid and oxide of glyceryl.

Butter of Cacao.—This substance is the fatty matter of the chocolate nut. The *theobroma cacao* is the tree producing this nut, and is grown extensively in Demerara, Berbice, the West Indies, and South America. There are numerous species of this tree, bearing different kinds of fruit, both as to form, size, and the number of seeds which they contain. They vary also in the yield of oil, not only according to the species whence obtained, but also to the mode of treatment after being gathered and removed from the fruit. The average size of good nuts is that of the sweet almond, but rather more thick. Those from Caracas or New Granada, are especially remarkable for the large proportion of fatty matter they contain. Cocoa and chocolate are preparations of the nut of this tree, produced by roasting and grinding, and sometimes with

the addition of various other ingredients, as sugar, starch, gum, treacle, arrowroot, *et cetera*. LAMPADIUS analysed the kernel of the cacao nut, with the following results :—

	Per cent.
Fat oil,.....	53.10
Azotized substances,	16.70
Starch,.....	10.91
Gum,.....	7.75
Coloring matter,	2.01
Woody fibre,.....	0.90
Water,.....	5.28
Ash,.....	2.00
Loss,.....	1.35
	100.00

The chocolate nut also contains an alkaloid, discovered by WOSKRESENSKY, and termed *theobromine*. It is strikingly analogous to *caffein*, and especially remarkable for the large quantity of nitrogen it contains, amounting to 35.4 per cent. It is white, pulverulent, and of a bitter taste, and is nearly insoluble in water, alcohol, or ether.

Butter of cacao is obtained from the powdered kernels after being mixed with ten times their weight of boiling water, by expression in canvas bags, between heated iron plates. One pound of cacao yields from five to six ounces of oil. It is purified by long boiling with water, or on the small scale by boiling alcohol. The crude oil is yellowish and has the smell and taste of the nut. In the pure state it is colorless, inodorous, and tasteless. It is not liable to become rancid, and hence the great value of the nut as an article of diet. Its consistence is about that of tallow and its flavour rather agreeable. Its specific gravity is 0.91; its melting point about 120°. It is for the most part a crystalline combination of olein and stearin, fusing at about 85°. Cacao butter is readily soluble in hot alcohol, but is deposited on cooling. Ether also dissolves it. It may be employed in the manufacture of soap and candles. Cacao butter soda-soap is an agreeable toilet article for persons troubled with a rough skin or chopped hands. From its little liability to become rancid, cacao butter is peculiarly adapted to the preparation of such ointments as are to be kept for a length of time.

Laurel Oil.—This oil, termed also *oil of bays*, is imported from Trieste. It is procured from either the fresh or dried berries of the sweet bay—*laurus nobilis*. This plant is cultivated in the South of Europe, and bears a fruit of a bluish-black color, oval, and about the size of a small cherry. According to the analysis of BONASTRE, laurel berries have the following composition :—

	Per cent.
Volatile oil,.....	0.8
Laurin,	1.0
Fixed oil,	12.8
Stearin,	7.1
Resin,	1.6
Uncrystallizable sugar,	0.4
Gummy extractive,.....	17.2
Bassorin,.....	6.4
Starch,.....	25.9
Lignin,.....	18.8
Soluble albumen,.....	traces
Acid,	0.1
Water,.....	6.4
Salts,	1.5
	100.0

Laurel oil is obtained from the berries by boiling and by expression. According to DUHAMEL, the berries are bruised in a mortar, boiled for three hours in water, and then pressed in a canvas bag. The oil exudes with the decoction, and when cold, floats on the surface. The dried berries are steamed until thoroughly soaked, and then quickly pressed between heated iron plates. By the latter process they yield one-fifth of their weight of oil.

Laurel oil is of a greenish color, of the consistency of butter, and of a peculiar and characteristic smell. It melts at about 100°. It is partially soluble in alcohol, and completely so in ether. It consists for the most part of a peculiar variety of stearin, named *lauro-stearin*; the residue is a green liquid fat, probably olein. Laurel oil is saponifiable. It is occasionally employed in medicine as a stimulating liniment in sprains and bruises, and in paralysis. Its principal use, however, is in veterinary medicine.

Piney Tallow.—This fat is obtained from the seed of the *vateria indica*, a tree which is extensively grown on the coast of Malabar. The fat is not well-known in this country. A sample of it was shown in the Great Exhibition, and attracted much attention. To obtain it the seeds are boiled with water for some time, and on cooling, the concrete fat is removed. According to BABINGTON, its ultimate constituents are 77 of carbon, 12.3 of hydrogen, and 10.7 of oxygen. It is a white solid oil, fusible at 97°. It forms excellent material for soap and candles. Its great advantage over some other oils is, that the candles made of it do not give out suffocating acrid vapors when extinguished.

Butter of Nutmegs.—The fruit of the *myristica moschata* by expression yields this oil—known also as oil of mace. The nutmeg-tree grows to a height of twenty to twenty-five feet, and in appearance resembles a pear-tree. It is cultivated in the Moluccas, and in the East and West Indies. Several varieties of nutmegs are met with in commerce. Their principal consumption is for dietetical purposes. BONASTRE'S analysis of these nuts is as follows :—

	Per cent.
Volatile oil,.....	6.0
Liquid fat,	7.6
Solid fat,	24.0
Acid,	0.8
Starch,	2.4
Gum,.....	1.2
Lignin,.....	54.0
Loss,	4.0
	100.0

The process employed in the extraction of the fixed oil is bruising the nut to a paste, inclosing the mass in a bag, and submitting it for some time to the action of steam. The whole is then placed between heated metal plates, and subjected to long-continued expression. The yield of nutmeg butter is about twelve per cent. of the weight of the nuts employed. It is imported in oblong cakes, covered with leaves, and weighing about twelve ounces. It is of a reddish-yellow color, firm consistence, and possesses the agreeable smell and taste of the nutmeg. According to SCHRADER, this oil consists of fifty-two per cent. of a liquid, and forty-four per cent. of a solid fat, with four of volatile oil. The solid portion consists for the most

part of a peculiar fat, named *myristin*, or *sericin*. The liquid oil is yellowish or brownish, soluble in cold alcohol, and in ether. Butter of nutmegs is readily saponifiable. It is an article also of the *materia medica*, and is sometimes employed as an unguent in cases of rheumatism and palsy. A spurious kind is said to be occasionally met with, composed of lard which has been boiled with powdered nutmegs, and flavored with sassafras. It may be readily known from the genuine butter by its insolubility in boiling alcohol.

Some other varieties of solid oil are imported in small quantity from the East Indies, but are not of sufficient importance to call for detailed notice; certain it is, however, that should accidental circumstances at any time occasion a scarcity of the oils now generally applied to manufacturing purposes, an almost inexhaustible supply of them might be obtained with little difficulty, and would probably replace the more common oils, without disadvantage either to the manufacturer or the consumer.

DRYING OILS.—The drying oils differ from those above described, by their peculiar behavior on exposure to the air, and also, as previously noticed, by the difference in their behavior under the influence of nitrous acid. The cause of the singular property of drying in contact with atmospheric air is not distinctly understood, but is usually attributed to some peculiarity in their olein.

LINSEED OIL.—This, the most important of the drying oils, is obtained by expression from the seeds of the common flax, *linum usitatissimum*. This plant is extensively cultivated in this, as well as other European countries, both for its fibre, used in producing thread, and for the oil obtained from its seeds. It is said to be a native of Britain, and yet it appears that flax-seed was not sown in England till about 1533, when it was directed to be sown for the production of flax for the manufacture of fishing nets. The seeds, commonly termed lintseed or linseed, are small, oblong, smooth, and pointed at one extremity. Externally, they are of a glossy brown color; and internally, yellowish white. Their taste is oily and mucilaginous. The mucilage, however, for the most part exists in the seed coats, and not in the nucleus, the latter being the richest in oil. The following analysis of linseed is by MEYER:—

	Per cent.
Fat oil,.....	11.265
Wax,.....	0.146
Acrid soft resin,.....	2.488
Resinous coloring matter,.....	0.550
Yellow extractive and tannin,.....	1.917
Sweet extractive, malic acid, and salts,.....	10.884
Gum,.....	6.154
Nitrogenous mucilage, acetic acid, and salts,.....	15.120
Starch, with salts,.....	1.480
Albumen,.....	2.782
Gluten,.....	2.932
Husk,.....	44.382
	100.000

According to GMELIN, the ashes contain oxide of copper. The proportion of fat oil contained in the seed is certainly much greater than that given in the preceding analysis; for, by expression in the cold, the yield of oil is from twenty-one to twenty-two per cent. of the seeds, and by the assistance of heat, combined

with a more powerful and long-continued pressure, as much as twenty-eight per cent. may be obtained. If a very pure oil be required, the process of cold expression must be pursued; a very good oil, however, may be obtained by a steam heat, not exceeding 200°. The ordinary method of getting rid of the large quantity of mucilage is by torrefaction, after which the seeds are bruised and submitted to pressure. The *marc* remaining after the expression of linseed oil is generally known as *oil cake*, and is an article of great importance to the agriculturist, being extensively employed, especially in the winter season, as food for cattle. By far the best oil cake is that from English seed. Independent of its use as an article of food, oil cake is an excellent medicine for cattle, as a preventive of constipation, besides which, it gives to the hide a *sweetness of coat* unattainable by other means. Foreign oil cake is certainly largely adulterated with the husks of other seeds, and many circumstances seem to lead to the conclusion, that the adulterant has been added previous to the expression of the seed. In this case, of course, foreign linseed oil must also contain spurious admixture, and will be less valuable as a drying oil than that expressed in this country. As regards oil cake, the consumer is assured that he will best consult his own interest by, in every case, submitting a sample to the inspection of a competent chemist previous to purchasing, for, in addition to the admixture of less nutritious seed coats, as bran, *et cetera*, many other positively injurious substances, as sawdust, clay, and other earthy matters, are frequently found in English, as well as foreign cake; and, in a case recently brought to the notice of the Editor, in which some sheep had died suddenly, the only cause to which death could be attributed was the enormous quantity of *sand* which he found in the stomach, and which the Editor considered could only have been introduced therein in admixture with the cake given as food.

The linseed meal—*farina lini*—of the Edinburgh Pharmacopœia, is powdered oil cake, and is frequently employed in this country as an emollient poultice. In this state also, it is often adulterated with bran, sawdust, *et cetera*. NORMANDY gives as a test of the genuineness of linseed meal, that when treated with ether it should yield fifty-three per cent. of oil. This, however, is manifestly a mistake. Linseed itself contains less than thirty per cent. of oil, of which, in most cases, twenty-five are extracted by expression, so that it will rarely happen that more than five or six per cent. at the utmost can be present in official linseed meal. Some medical practitioners prefer what they suppose to be simply powdered linseed, but which, in reality, is powdered oil cake, subsequently mixed with a greater or less quantity of oil. In this case, of course, a larger proportion of oil may be found on examination, but it by no means follows that meal containing less than fifty-three per cent. of oil should be designated as spurious. But to return from this digression to the consideration of oil of linseed. If extracted by cold expression, when it is termed *cold drawn* linseed oil, it is paler colored, less odorous, and has less taste, than that obtained by the aid of heat. In the latter case, the oil is of an amber or brownish-yellow color, and

also more susceptible of rancidity than when cold drawn. The smell and taste of linseed oil is highly characteristic and peculiar to itself. Its specific gravity, according to SAUSSURE, is 0.9395 at 52°. It dissolves in five parts of boiling, and forty of cold alcohol, and in about one and a half times its volume of ether. According to SACC it consists of one equivalent of margarate of glyceryl, and ten equivalents of a peculiar fat, termed *linolein*. If cooled down to about minus 20°, it may be kept some time without suffering any important change. After the expiration of a longer or shorter period, however, dependent upon the precise temperature, it becomes darker-colored and deposits a portion of its solid constituent along with coloring matter; at a few degrees lower, it becomes entirely converted into a concrete yellow mass. Linseed oil may be completely decolorized by the action upon it of protosulphate of iron in conjunction with sunlight. A solution of two pounds of the salt in two and a half pounds of water, is poured into a flask containing two pounds of linseed oil, and the whole is submitted to sunlight for some weeks with frequent agitation. The oil becomes limpid and colorless, and may be drawn off by a siphon or otherwise.

Linseed oil is most largely used in the manufacture of paints and varnishes. Its drying properties, as previously remarked, are much increased by boiling with a small quantity of litharge, or of peroxide of manganese. It is used also in the preparation of printers' ink, in the preparation of black enamel for leather, and in the varnishing of oiled silk. For the finer purposes of art, it is purified and decolorized as above directed. In white-lead works, linseed oil is bleached by sulphuric acid, and the small portion of acid always remaining in the oil after this operation, has the good effect—by converting into sulphate any hydrate of lead that may be present in the white-lead with which it is ground—of preventing the production of the yellow higher oxide when the paint is exposed to the air. A method of purification especially to be recommended when the oil is to be used in the preparation of varnish, is to triturate the oil with dry sulphate of lead in sufficient quantity to form a milky mixture. After a week's exposure to light, and with frequent agitation, the mucus and parenchymatous matters deposit with the sulphate of lead, and leave the oil perfectly clear. The oil will then, after some time, become quite white. The precipitated matters form a compact membrane above the salt of lead, and become so hard that the supernatant clarified oil may be poured off. The lead sediment may again be used for the same purpose. Varnish so prepared is especially valuable in those cases where the presence of a salt of lead would be injurious—as for instance with lac colors, with sulphide of cadmium, and other pigments containing sulphur. When long kept in a bottle only half filled with it, the linseed oil becomes more thick, and does not dry as well as before. By this treatment, however, it acquires the property of comparatively ready solubility in alcohol, and is therefore added with advantage to several spirit varnishes to diminish their brittleness.

The substance known as *caoutchouc* of oils is obtained from linseed oil as follows:—The oil is exposed for some time, as in the preparation of printers' ink, to a

high temperature, when it becomes converted into a dark tenacious mass. If this be boiled for some hours with dilute nitric acid, it acquires a thick consistency, and becomes hard on exposure to the air, but softens again by the heat of boiling water, and again hardens to a consistency resembling that of caoutchouc, for which, indeed, it may in some instances be substituted. This singular body is soluble in oil of turpentine, in bisulphide of carbon, and in dilute alkaline solutions; from the latter it is thrown down unaltered on the addition of an acid. Other drying oils, beside linseed, yield a similar substance, though not so abundantly. Linseed oil is frequently adulterated with resin or colophony. This may be detected by digesting the oil with alcohol, decanting the latter, and adding acetate of lead, when the appearance of a white precipitate is indicative of this falsification.

By digestion with alkalies or with metallic oxides, linseed oil is easily saponified. The proportion of oxide of glyceryl in this oil is greater than in most other oils, and hence, by far the most advantageous method of preparing glycerin, is by moderately heating this oil with oxide of lead.

Walnut Oil.—This drying oil is derived from the kernels of the *juglans regia*, or walnuts. The nuts are freed from their ligneous shells, inclosed in bags, and submitted either to cold or hot pressure. That prepared by hot pressure has a peculiar taste and smell, the latter being especially recognizable during its combustion. The oil obtained by cold expression is pale, yellowish-green or almost colorless, has an agreeable odor and taste and a sirupy consistency. If colored, it loses the greenish hue after some time. It congeals at about the same temperature as linseed oil, and possesses the property of drying by exposure in even a higher degree than the latter. In drying, it absorbs fifteen and a half times its volume of oxygen, at the same time giving off carbonic acid to the amount of two-fifteenths of the oxygen absorbed. The hot-pressed oil is usually high colored, has a powerful odor, and contains large quantities of mucilage. The specific gravity of walnut oil, according to SAUSSURE, is 0.9283 at 52°; 0.9194 at 76°; and 0.874 at 200°.

It is principally used in painting, and by varnishers, and being comparatively clear and colorless, is especially valuable as the vehicle for flake white, and other pigments, when it is desired to preserve the brilliancy of their tints. When fresh, it is occasionally employed for culinary purposes, but when rancid, it is purgative. Sometimes also it is employed as a source of light.

Poppy Oil.—The seeds of the poppy—*papaver somniferum*—yield this oil by expression. This plant appears to grow wild in some parts of Great Britain. It is extensively cultivated in Hindostan, Persia, Asia Minor, and Egypt, on account of the opium obtained from it. In Europe, the poppy is cultivated for the capsules or *poppy heads*, either as medicinal agents, or for the oil obtained from their seeds. No analysis of the seeds appears to have been made. Poppy oil is whitish-yellow, inodorous, with an agreeable almond flavor; it much resembles olive oil, for which, as already noticed, it is sometimes used as an adulterant. When pure, it is much less viscous than most oils, and remains liquid

even to 0°. Its specific gravity is 0.9249 at 60°. It is soluble in about twenty-five parts of cold, and six of boiling alcohol, and in ether in all proportions. It is used as a means of detecting the presence of spirit of turpentine in essential oil. In France and on the Continent, it is frequently used for culinary purposes, as a substitute for olive oil. When its drying properties are increased by treatment with litharge, it is frequently used in painting. It is employed also for illuminating purposes.

Hemp-seed Oil.—This oil is extracted from the seeds of common hemp—*cannabis sativa*. The plant grows wild in Persia, Caucasus, and the North of India. It is cultivated in various other countries. The seeds are small, ash-colored, shining, nut-like bodies. They are employed for feeding cage birds, and, according to BURNETT, possess the singular property of changing the color of the plumage of bullfinches and goldfinches from red and yellow to black, if the birds are fed on the seeds for too long a time, or in too large a quantity. The following is their composition as obtained by BUCHOLZ :—

	Per cent.
Fixed oil,.....	19.10
Resin,.....	1.60
Sugar and extractive,.....	1.60
Gummy extract,.....	9.00
Soluble albumen,.....	24.70
Ligneous fibre,.....	5.00
Husk,.....	38.30
Loss,.....	0.70
	100.0

The oil is extracted principally in Russia. The yield is stated by PEREIRA to amount to twenty-five per cent. of the seeds. This, however, is only in extreme cases, the quantity usually obtained rarely exceeding from fifteen to twenty per cent. The oil has a greenish-yellow tinge, a disagreeable smell, and a mawkish taste. The specific gravity at 52° is 0.9276; at 5° it becomes thicker, and at *minus* 16° it is solid. It is readily soluble in boiling alcohol, and in about thirty parts of this spirit when cold. It is used in painting, and in the preparation of a soft soap. It is occasionally employed in Russia as a source of light, but is apt to form a viscid adherent varnish, which impedes its passage through the lamp.

CASTOR OIL.—*Huile de ricin*, French; *ricinusöl*, German; *oleum ricini*, Latin. This oil is extracted from the seeds of the *palma christi*, or common ricinus, which is cultivated in the East and West Indies, and in the United States of America.

The plant yielding it was known in the most ancient times; indeed many suppose the plant called the *gourd*, mentioned in JONAH, to be the same as that now recognized as the castor oil plant. The Egyptians were certainly acquainted with it, as CAILLAUD discovered its seeds in some Egyptian sarcophagi, conjectured to have been upwards of four thousand years old. It was known to the ancient Greeks, and is alluded to by HERODOTUS and HIPPOCRATES, the latter of whom employed its root in medicine. The Latins gave it the name of *ricinus*, whence its botanical appellation. In this country the *ricinus communis* is an annual, and seldom exceeds four feet in height. In other countries

it is said to be perennial, arborescent, growing to the height of fifteen or twenty feet, and of many years' duration. It has large vine-shaped leaves, green spikes of flowers, and rough capsules containing ovate shining black seeds, spotted with grey. The subjoined analysis of the seeds of this plant is by GEIGER :—

	Per cent.
Seed coats,.....	{ Resin and extractive,.... 1.91
	{ Brown gum,..... 1.91
	{ Ligneous fibre,..... 20.00
Nuclei of the seeds,...	{ Fatty oil,..... 46.19
	{ Gum,..... 2.40
	{ Albumen,..... 0.50
	{ Ligneous fibre and starch, 20.00
Moisture,.....	7.09
	100.00

In opposition to GEIGER's results, BUCHANAN states that the residue freed from oil consists for the greater part of emulsion, is not colored blue by iodine, and instead of starch contains sugar; for an emulsion of castor seeds, mixed with yeast, undergoes the alcoholic fermentation at a low temperature.

Extraction of the Oil.—Various methods have been adopted for the preparation of castor oil. The expression of the seeds in the cold, though a more tedious process, yields a much superior oil to that obtained when the pressure is assisted by heat. Previous to expression the seeds should be deprived of the outer coating or shell, when they yield an oil nearly colorless, or with a slight yellow tint.

According to SOUBEIRAN, BUSSY, and LECANU, all processes in which heat is employed are objectionable, as the oil is rendered acrid from the liberation of fatty acids. In the American Dispensatory, on the contrary, the application of heat is stated to improve the oil by volatilizing a disagreeable acrid principle; and hence the almost universal practice in America is first to submit the seeds to gentle torrefaction, the heat being insufficient to scorch or decompose them. They are then introduced into a powerful screw press, and submitted to pressure. A whitish oily liquid exudes, which is boiled with a considerable quantity of water in iron boilers, and the impurities skimmed off as they rise to the surface. The coagulated albumen forms a layer between the oil and the water, and the starch and gum are retained in solution in the water. The clear oil is next drawn off and boiled with a small quantity of water until aqueous vapor ceases to rise, and till a small portion of the liquid taken out in a phial preserves a perfect transparency on cooling. The effect of the latter operation is to clarify the oil, and render it less irritating, by driving off volatile acrid matter, the quantity of which is doubtless much increased by the process of torrefaction to which the seeds are subjected. The process of cold expression, purification by subsidence and decantation, is also employed in America, though on a much less extensive scale.

In England castor oil is expressed by BRAMAH's hydraulic press, or by the common screw press, in a room artificially heated. It is purified by rest, decantation, and filtration, and bleached by exposure to light on the tops of warehouses. In Calcutta, according to PEREIRA, the process is as follows :—The fruit is shelled by women; the seeds are bruised between rollers, then placed in hempen cloths, and pressed in

the ordinary screw or hydraulic press. The oil thus procured is subsequently heated to 212° with water, in a tin boiler, by which the albumen is coagulated, and, with the mucilage, separates as a scum. The oil is then passed through flannel, and run into square tin cases. The best oil of this variety is sold in London as *cold-drawn castor oil*. According to AINSLIE castor oil is obtained in the East Indies also by decoction, and this process is likewise pursued in the West Indies.

The process of FIGUIER is now followed on the Continent of Europe on a considerable scale. It consists in mixing the seeds, first deprived of their outer coating and bruised into a paste, with alcohol. This mixture is inclosed in canvas bags, and submitted to pressure. Part of the alcohol is recovered by distillation of the mixture of oil and spirit; the residue is then mixed with a large quantity of water, when the oil rises to the surface, and is drawn off. It is again heated to remove traces of moisture and then filtered. This process is more expensive than those previously given, and the product is inferior.

After its arrival in this country, foreign castor oil is filtered, and bleached by exposure to solar light on the tops of warehouses. Of the several varieties met with in commerce, the East Indian castor oil is the most abundant. It is an oil, in every respect, of good quality, but inferior to English cold-drawn oil. American oil rarely finds its way into this country. It has a less acrid taste than the East Indian variety, but is objected to because at a low temperature it congeals quickly, deposits a white substance termed margaritin, and becomes opaque.

Properties.—When very pure, castor oil is a thickish, viscid fluid of a bright yellow hue, with a slightly nauseous smell, and a mild, somewhat sweetish taste, succeeded by a slight sense of acrimony. The oil of commerce is, however, frequently of a greenish, and occasionally of a brownish color, with a hot acrid taste. Its specific gravity is, according to SAUSSURE, 0.9801 at 49°; 0.9699 at 52°; and 0.9575 at 76°; and is, consequently, heavier than most other fixed oils. Its composition and properties are essentially different from those of other oils. It is soluble in absolute alcohol in all proportions. Spirit of wine, of specific gravity 0.8425, dissolves about three-fifths of its weight. It is also readily soluble in ether. This oil forms the connecting link between the siccative and non-drying oils. By long exposure to the air it becomes rancid, but gradually hardens without becoming opaque. It retains its fluidity even at a temperature of 0°. At a lower degree, it congeals into a transparent yellowish mass. The action of heat upon castor oil has been particularly investigated by BUSSY and LECANU. When heated in a retort, so as to distil over about one-third, there remains a substance, solid at ordinary temperatures, having the appearance of a yellowish porous body resembling caoutchouc. It requires a high temperature for its decomposition, and is easily inflammable, without undergoing fusion. It is insoluble in water, alcohol, ether, and in the fixed and volatile oils. The alkalies convert it into a species of soluble soap. The products of distillation are a little gas, and a liquid containing acetic, ricinic, ricinoleic, and margaritic acids, and an

odorless, colorless, volatile oil, which crystallizes on cooling.

Adulteration.—Castor oil is said to be frequently adulterated with other fixed oils, and especially with lard oil. For the detection of this falsification, the Edinburgh Pharmacopœia directs that it be examined as to its solubility in alcohol, which dissolves its own volume of castor oil. This test, however, is of no practical value, as the solubility of other fixed oils is greatly increased by admixture with castor oil, and even a third of its weight of another oil may be present, and still a perfect solution be obtained with an equal volume of alcohol. Of the different kinds of genuine oil, English is, according to PEREIRA, the most soluble, and East Indian, the least soluble, in rectified spirit. A far more dangerous fraud than the above, is the occasional one of adding a small proportion of *croton* oil, with the view of increasing its purgative activity, and this, unfortunately, is not of easy detection.

Physiological Effects.—On animals generally, castor oil acts as a laxative or gentle purgative. Its great advantage over other purgatives is the rapidity of its action—usually not more than two or three hours after its exhibition. It not unfrequently occasions nausea, or even vomiting, but this effect is rather to be attributed to its disgusting flavor than to any positively emetic property. Some continental writers have stated it to be very unequal in its action, sometimes operating with considerable violence, and at others with great mildness. This is not found to be the case in this country, though PEREIRA readily admits that a difference in the mode of its preparation may materially affect its aperient property. As obtained by boiling, it is deeper colored, more acrid, and more susceptible of rancidity, than the cold drawn oil, and at the same time is undoubtedly possessed of more active properties. The bleaching process, although it removes color and taste, is also injurious to the oil, often rendering it almost inactive; and therefore, medicinally, the pale straw-colored oil—not absolutely tasteless, and with a certain degree of smell—is to be preferred. Castor oil is employed principally in cases of inflammation of the stomach, in spasmodic affections of the bowels, especially in lead colic, in other internal inflammatory and spasmodic diseases, and as a purgative in habitual costiveness. The dose is from two drams to two ounces, and it may be taken swimming on the surface of milk or coffee, warmed and beaten up with the yolk of egg or mucilage of tragacanth, or with the addition of a little orange wine. The vessel from which it is taken should be previously warmed, and moistened with water or other liquid. The nauseous clammy taste is most easily removed by masticating a crust of bread or a little oatmeal.

Statistics.—The quantity of castor oil imported annually during a period of seven years was as follows:—

	Pounds.
1843,.....	1,051,792
1844,.....	1,223,264
1845,.....	1,801,632
1846,.....	1,487,168
1847,.....	451,584
1848,.....	513,856
1849,.....	1,084,272

Grape-seed Oil.—This oil, called also *oil of wine-stones*, is extracted by pressure from the seeds of the grape—*vitis vinifera*. The yield is sometimes to the amount of twenty-two per cent. Its color is at first pale-yellow, but after some time it assumes a darker tint, and becomes at the same time viscous, thick, and rancid. When fresh and pure it has little odor, and a very mild taste, and hence is useful for culinary purposes. Its specific gravity is 0.9202 at 59°. It is used principally as an article of diet.

Cotton-seed Oil.—The seeds of the cotton plant—*gossypium barbadense*—yield an oil which may at no distant period become an important article of commerce. The plant is grown principally in the Southern part of the United States of America, but also in India, China, and other warm climates. Owing to the enormous quantity of cotton annually produced, there must always be an abundance of seed, which it is desirable to convert to some useful purpose. The subject has long engaged the attention of parties interested in the promotion of the useful arts. Even so far back as 1785, the Society for the Encouragement of Arts and Commerce offered a prize for the manufacture of oil from cotton-seed on the large scale, but no successful claimant has yet appeared. It has, however, been extracted to a certain extent in Egypt, America, and India. The great difficulty in the way of its introduction appears to have been that of effecting its purification. Of late years, this oil has attracted a greater share of attention, and means have been devised of purifying it, and removing the dark color which it possesses in the raw state. Even now, however, large quantities of cotton-seed are annually destroyed, as far more is produced than is required for the crop of the succeeding year, and this has hitherto, for the most part, been thrown away as useless, or in some cases applied as a manure; still it is now in some solitary instances collected and exported for the manufacture of oil and oil-cake. A sample of the oil and expressed cake were shown in the Great Exhibition by R. BURN of Edinburgh, and of raw and bleached oil by DE GÉMINY of Marseilles, to whom prize medals were awarded. The latter was from Egyptian seed.

Croton Oil.—This acrid oil is extracted from the seeds of the *croton tiglium*, and is imported from Madras and Bombay. In size and shape these seeds much resemble castor-seeds. They have no smell; their taste is at first mild and oleaginous, afterwards hot and acrid. Besides BRANDE, PELLETIER, and CAVENTOU, Dr. NIMMO also examined them. The result of BRANDE'S analysis is subjoined:—

Volatile oil,	traces.
Fixed oil, with crotonic acid and crotonin,	17.00
Crotonates and coloring matter,	0.32
Brownish-yellow resin,	1.00
Stearin and wax,	0.65
Extractive, sugar and malates of potassa and lime,	2.05
Starch, with phosphate of lime and mag- nesia,	5.71
Gum and gummosin,	10.17
Albumen,	1.01
Gluten,	2.00
Seed coats and ligneous fibre,	39.00
Water,	22.09
	100.00

Croton oil is extracted by expression from its seeds. That of the shops is very impure, being a mixture of the oil with other constituents of the seeds. DUMAS gives the process for obtaining it as follows:—The crushed seeds are submitted to the press, and the oil that flows out is allowed to stand from twelve to fifteen days to deposit; it is then drawn off and filtered. The expressed cake is treated with twice its weight of rectified spirit, and heated in the salt-water bath. The alcohol dissolves a large quantity of the oil remaining in the *marc*, and is separated from it by evaporation. Sometimes, the seed, freed from their husks, are pulverized and treated at once with spirit; the mixture is heated in the salt-water bath, allowed to cool, inclosed in a bag, and pressed. The alcohol is afterwards removed from the oil by distillation. Croton oil is of a brownish-yellow color, has a very disagreeable characteristic odor, and a strongly acrid taste. It is soluble in alcohol and in ether. In doses of one drop, it operates on man as a violent purgative. It appears to consist of a mixture of a fatty oil with another very acrid substance, very soluble in cold alcohol, and containing a large quantity of crotonic acid, both free and in combination with oxide of glyceryl, and with magnesia. The combination of the acid with the latter base was supposed by BRANDE to be a peculiar alkaloid.

ANIMAL OILS.—It is unnecessary again to allude to the origin and formation of animal fats, the various theories concerning which have been previously fully detailed and discussed. It will be sufficient to say here that by far the greatest proportion of the fat of animals is the result of the deoxidation of the amylaceous principles of vegetal food, and that the fat originally formed and existing in vegetal food also accumulates, undergoing considerable modification in the animal body. Hence the fat of the *herbivora* is that which most closely resembles the fat of vegetables; and the fat of the *carnivora*, having undergone a still further modification in the animal body, is that which most widely differs from vegetal oils. It has also been already noticed in what part of the animal fat is for the most part secreted. It is contained in what is termed adipose membrane, and may be obtained by exposure to a sufficiently high temperature to liquefy the fat, and tear asunder its including cells. To assist the operation, the fat should be divided into small pieces, so as to allow the more uniform influence of heat; and it is important that the melting process be performed before any putrefaction of the membrane, or of other fibrous and fleshy accidentally adhering matters, has taken place. The fat is usually melted in an open copper exposed to the direct action of the fire, and after fusing for a considerable time, the membranous matters collect at the surface. These are removed, and after having been pressed to remove adhering oil, they form *greaves*, sometimes termed also *cracklings*, from their crispy nature, and in the form of flat cakes are sold as food for dogs, as manure, and for the production of yellow prussiate of potassa. The melted fat is passed through a sieve into another copper, where it is washed with a quantity of boiling water. The impurities settle down with the water, and the fat is drawn off into tubs and allowed to cool.

In France, and on the Continent, another method is adopted for the separation of fatty matters from the cells or tissues in which they are confined. The fatty matter is placed in contact with very dilute sulphuric acid for a few days, after which the fat is removed from the macerating vessel, and with the addition of about half its weight of a little stronger acid, put into a suitable wooden vessel, and subjected to a jet of steam, which soon causes the whole to boil. Under the influence of heat and of the dilute acid, the albuminous tissue which envelopes the fatty matter is rapidly destroyed, and the latter set free floats on the surface of the boiling water; after which the jet of steam is stopped, and the liquid fat is drawn off into a proper receiver. The addition of a little strong acid again prepares the melting-vessels to receive a new charge of the digested fat, which may also be drawn off after a short time. Larger pans are required in this operation than in the former, to perform the same amount of work; but the work is done more quickly. The animal matters remaining in the pan can be used as manure, or, after mixing with a little sawdust, as fuel. By this method, also, the operation of fat-melting is rendered perfectly safe, and the highly disagreeable odor characterizing the vicinity of establishments devoted to this purpose, is entirely removed.

The variable consistency, color, and odor of the different fats depends for the most part upon the kind of animal whence obtained, its climate, and its food; but male animals generally yield a firmer fat than female. A good quality of fat can come only from a healthy animal, and winter fat is better than that taken in summer. According to WATT, the fat of an animal is more solid the further it exists from the surface of the body; and the delicacy of the cellular tissue enveloping the fat is in proportion to the consistency of the latter. He is of opinion also that the fat of animals in temperate and tropical climes is much more firm than that from those of cold regions. This statement, however, requires additional experience and observations before it can be received as a law of the animal economy.

Fats always melt at a lower temperature than the solid acid which they yield by saponification; but the melting point varies with the part of the animal whence extracted. They are generally tasteless and neutral when fresh, but acidify and become rancid by exposure to air. Their specific gravity is below that of water, and they are all more or less fusible. Alcohol partially dissolves them, but they are wholly insoluble in water. In carnivorous animals the fat is usually soft and rank-flavored; in the ruminants nearly inodorous. In well-fed young animals it is generally white and abundant, and in the old, yellowish and more scanty.

The following is a list of the principal animal fats, with the fusing point of each:—

	Fusing point.
Badger fat,.....	86·0°
Beef suet,.....	98·5
Calf suet,.....	136·8
Camel suet,.....	131·0
Cows' butter,.....	79·7
Dog fat,.....	79·75
Elephant fat,.....	82·0
Fox fat,.....	129·0
Hare fat,.....	117·5
Hogs' lard,.....	80·5

" beef suet,.....	111·0
" hogs' lard,.....	109·0
Neat's-foot oil,.....	liquid below 32·0

TALLOW.—Under this name is included the fat of oxen, sheep, goats, deer, and some other animals. They all consist for the most part of stearin, with a little olein, while some also contain certain quantities of a particular ingredient which communicates to the fat characteristic properties. As far as their application is concerned, they are alike in properties. As a source of light, tallow is more or less valuable according to its greater or less degree of solidity; and is found from experience to be more solid, and consequently more valuable, in animals fed upon dry, ripe fodder, than in such as are supplied with green food or grains. Hence the tallow imported from Russia, where the animals are fed for eight months upon dry fodder, is generally superior to that produced at home.

The process for the separation of tallow from the membrane and tissue in which it is included in the animal body, is the same as that given for preparing the animal fats in general. The methods of purification and clarification are modified according to the purpose to which it is to be applied, and the greater or less degree of cleanliness, or freedom from foreign matters, of the fat itself. To separate the solid and liquid constituents of tallow, it is melted, and constantly stirred whilst in the act of congelation. It is then pressed in woollen bags, at a temperature of about 95°; the olein which is thus pressed out still retains much stearin, but by repeatedly pressing in a similar manner, lowering the temperature each time by a few degrees, an olein is obtained, fluid at 32°, and the stearin is hard and granular. The hardening and whitening of tallow may be accomplished by other means than pressing, a description of which will be found under the article CANDLE. Also, for further information upon this and other of the following fats, see vol. i., page 413 *et sequitur*.

Tallow Oil.—The liquid fat separated from tallow by pressure is known under this name. The best method of obtaining it consists, according to MORFIT, in steaming the tallow in wooden tubs for several hours, drawing off the upper clear portion after sufficient repose for subsidence of foreign matters, and gradually cooling in large tubs between 70° and 80°. These tubs are provided with a cullendered diaphragm, about six inches from the bottom, and which should be covered with coarse flannel cloth. During repose, the solid portion of the tallow separates in granules from the superstratum of fluid olein, and deposits upon the diaphragm, thus allowing the liquid olein to percolate upon the opening of the cock at the bottom, and be drawn off into receivers. The solid residue, upon being subjected to pressure in Russian canvas bags, yields more olein, and itself remains hard and white. Tallow oil is thick and mushy, and admirably suited to the manufacture of the finer kinds of soap.

Beef Tallow.—The fat of oxen is firm and brittle,

4 K

has a yellowish-white color, and a slight but peculiar odor. It melts at a temperature of 100°, is insoluble in water, but soluble in forty parts of boiling alcohol of specific gravity 0.821. It consists of olein and stearin, in the proportion of three parts of the latter to one of the former. The solid constituent or stearin is white, granular, and crystalline. It melts at 111°, and again solidifies at 102°. It has about the same translucency as white wax. Its feel is not greasy, and in burning it gives a light similar to that of wax. It dissolves in absolute alcohol, to the amount of fifteen and a half parts in a hundred. The olein of beef fat is colorless, with only a slight odor. Its specific gravity is 0.913. One hundred and twenty-three parts are soluble in a hundred of absolute alcohol, at the temperature of 167°. Beef tallow is used principally in the manufacture of soap and candles.

Mutton Suet.—This fat is similar to the preceding, but is whiter. It is very firm and brittle, has scarcely any smell, is completely insoluble in water, slightly soluble in alcohol, and melts at temperatures between 100° and 106°. The solid portion of this fat, which amounts to seventy-four per cent., consists, according to HEINTZ, of stearin, margarin, and palmitin. It is white and lustreless. It begins to solidify at 99.5°, is translucent, and partially soluble in alcohol. The olein of mutton suet is colorless, has a slight odor of the flesh of the animal, and a specific gravity of 0.913. Eighty parts of it are dissolved by one hundred of absolute alcohol, at the temperature of 167°. In addition to these ingredients, mutton suet probably contains *hircin*.

Goats' Fat.—This fat resembles that of the ox, but it has a disagreeable smell, arising from the presence of a peculiar oily matter, first discovered by CHEVREUL, and termed by him *hircin*. It is liquid, and is found in the olein when the fat of goats is separated into its solid and liquid constituents. It is composed of oxide of glyceryl, united to a peculiar acid named *hircic*. Although *hircin* has not yet been obtained pure, CHEVREUL prepared the acid into the constitution of which it enters. His process was by saponification, decomposition of the soap by tartaric or phosphoric acid, and distillation of the mixture of fatty acids, when *hircic* acid is found in the receiver under the form of a colorless volatile oil. It has a capreous and acetic odor, an acid reaction, is difficultly soluble in water, and easily so in alcohol. With the bases it forms salts, of which that of baryta is difficultly soluble.

Cows' Butter.—This fat is derived from the milk of the cow. The various methods of manufacture, *et cetera*, have been treated under a separate article, page 397, *et seq.* It may be purified from buttermilk, cheese, and other impurities, by melting it, when the foreign matters subside with the water, and the pure oil rises to the surface. The characteristic odor and flavor of butter are owing to the presence of a small quantity of several peculiar fats, named—*butyrin*, *caproin*, *caprylin*, and *caprin*. These fats are combinations of oxide of glyceryl with the volatile butyric, caproic, caprylic and capric acids. According to HEINTZ, the solid portion of butter contains, besides palmitic acid, another acid which he terms the *butic*, and gives the following formula:— $C_{40}H_{40}O_4 = C_{40}H_{39}O_3, HO$.

Hogs' Lard.—This fat is generally prepared from the adipose matter of the omentum and mesentery of the hog. It is white, and has very little odor. It melts at 100°, forming a transparent and nearly colorless fixed oil. According to SAUSSURE, its specific gravity is 0.9302 at 60°. One hundred parts of boiling alcohol dissolve nearly three parts of its olein. Exposed to the air for some time, it becomes gradually yellow-colored and rancid, acquires a powerful odor and an acid reaction. In this process a volatile fatty acid is developed, which CHEVREUL considers analogous to caproic acid. Hogs' lard consists essentially of olein, stearin, and margarin, and by saponification gives nine parts of glycerin and 94.65 of a mixture of the fatty acids. According to BRACONNOT, the proportion of olein is sixty-two, and of the solid constituents thirty-eight per cent. The solid portion is without smell, translucent, dry, and granular. It melts at 109.5°. On congealing, it assumes an imperfectly crystalline texture.

Lard Oil.—This fluid oil is prepared from lard in the same manner as is directed for tallow oil. It is considered much superior to sperm or olive oil for greasing wool, and, from its low price, is largely used. It is usually sufficiently white and clear for use, and should on no account be bleached by chemical means, as it is liable to retain enough of the bleaching agent to injure its quality, and render it inapplicable for many purposes.

Human Fat.—The fat of man has a similar consistency to hogs' lard. Its melting point seems to vary with the part whence it is extracted. It requires forty parts of hot alcohol of the specific gravity 0.821 for solution. On cooling, the alcoholic solution deposits stearin, which, after re-solution and deposition, and pressure in blotting paper, may be considered pure. This stearin crystallizes in a mass of small needles. It is colorless, has little lustre, and melts at 122°. One hundred parts of boiling anhydrous alcohol dissolve 21.5 of this stearin, but the greater part is again deposited on cooling. The olein of human fat is a colorless oil, which solidifies in needles at about 24°. Its specific gravity at 59° is 0.913. It has no smell, but a sweetish taste. Alcohol dissolves more than its own weight of this olein. By saponification, human fat yields 9.66 parts of glycerin, and 95.24 of margarin and oleic acids per cent.

Under the name of *adipocere*, FOURCROY described a peculiar fatty substance found in a cemetery at Paris, and supposed to have been partly formed during decomposition. CHEVREUL has shown that this matter is the original fat of the body, which has resisted putrefaction, and is partly in the state of fatty acid, and partly as ammonia soap, with traces of lime and magnesian soaps. This substance may often be found in the neighborhood of graveyards.

Neat's-foot Oil.—This oil is obtained from the feet of oxen; and as it remains liquid below 32°, and is in other respects a useful lubricant, is much employed to oil machinery. In America, according to MORFIT, it is extracted by the following process:—The feet, as collected from the slaughter-houses, are soaked in cold water to remove the blood, and, after removing the sinews, are placed perpendicularly in sufficient boiling

water to cover the hoofs. In about a quarter of an hour they are to be taken out, and the hoof separated by a suitable machine. The next step is to joint them with a knife, to sever the toes from the large bone. The latter is boiled with water by steam, while the former, which are more obstinate in yielding their fat, are boiled in the open pan with water previously used for the large bones. After the boiling, the liquid is left to repose, so that the oil may rise to the surface and be drawn off. The collected oil deposits after some time a thick stratum of dirty semifluid fat, from which the clear supernatant portion must be decanted.

This oil consists of olein, margarin, and stearin; it is white and fluid at ordinary temperatures, but congeals a few degrees below 32°. It is very frequently adulterated with horse oil, common lard oil, bone fat, some vegetal oils, and even with fish oils. The pure oil is not liable to change or rancidity, and is used as a lubricant, and is especially useful for machinery exposed in cold situations, as in the case of church clocks, *et cetera*, which require an oil not liable to become concrete.

FISH OILS.—Certain fish, especially the *cetacea*, yield a greasy fluid or oil, called or named according to the fish whence it is extracted. All fish oils contain certain peculiar animal matters, which impair their illuminating power, but do not injure them for the purposes of the soapmaker. They are extracted by melting the blubber, and the foreign matters are then partially separated by steaming the oil and allowing it to repose. Under the term, *train oil*, are included, whale, seal, cod, shark, and all oils obtained from fish of a like nature.

Whale Oil.—This well-known fish oil is obtained by boiling the blubber of the *Balena mysticetus*, or great northern whale. The pursuit of this whale forms an important branch of industry, as well as a nursery for British seamen. It was formerly found on the east shores of Greenland, but of late years in Davis' Straits and the interior of Baffin's Bay. The whale fishers merely cut out the blubber, pack it into casks, and carry it to the seaports to be melted out. The carriage gives rise to an incipient decomposition of the animal matters, and of the fluids attached to the blubber, which, although it aids the melting, occasions the formation of a peculiar fat, termed *phocenin*, which is the cause of the disgusting odor which always accompanies train oil. The cellular tissue of the blubber thus becomes so broken down that the oil runs off by itself, when the whole is put into casks with wirework bottoms, such as are used in the melting houses. The oil is afterwards heated to 212° that the impurities may be more easily separate, and after standing some time, the clear oil is decanted.

In train oil the impurity is not mucus, as in the vegetal oils, but animal gelatin or glue, and, besides this, volatile, stinking matters. Some clarifiers use a solution of tannin for purifying it, which forms with the gelatin insoluble flakes; others employ metallic salts, as sulphate of copper or acetate of lead, which act in a similar manner. The nauseous odor is most easily removed by bleaching-powder.—*Knapp*.

The color of whale oil is brown, and it has a disagreeable fishy smell. Its specific gravity at 68° is

0.927. When cooled to 32°, it deposits stearin, and the residual oil is soluble in less than its own weight of boiling absolute alcohol; the stearin is soluble in about twice its weight of this liquid. When the solution is cooled, it deposits first white brilliant crystals, and afterwards crystals tinged with yellow, and a thick brown liquor remains. When this stearin is saponified and the soap is decomposed by an acid, glycerin is obtained, and about forty per cent. of fatty acids, with a little *phocenic* acid in admixture.

Seal Oil.—The seal-fishery is by far the most important part of the trade of Newfoundland, the annual catch of the fish being little short of three quarters of a million. The principal seals captured are the *hood* and *harp* seal, of which the latter is the best and most productive. The first operation after landing and weighing is the skinning, or separation of the fat from the skin; after which the fat is cut off, and transferred to the seal-vat. The latter consists of what are termed the *crib* and the *pan*. The crib is a strong wooden erection, from twenty to thirty feet square, and twenty to twenty-five in height. It is firmly secured with iron clamps, and the interstices between the upright posts are filled in with small round poles. The floor is of strong timber, capable of sustaining three or four hundred tons. The crib stands in a strong wooden pan, three or four feet larger than the square of the crib, so as to catch all the droppings. The pan is about three feet deep, and tightly caulked. A small quantity of water is kept on the bottom of the pan, for the double purpose of saving the oil in case of a leak, and for purifying it from the blood, and any other foreign matter of a higher density. The oil extracted by this process is all cold-drawn, which accounts for the disagreeable odor of seal oil. When the vats begin to run, the oil drops from the crib upon the water in the pan, and as it accumulates it is drawn off into casks, and is ready for exportation. The first running, which is caused by compression from its own weight, continues from two to three months, yielding what is termed *pale* seal oil, until from fifty to seventy per cent. is drawn off, according to the season, and also in proportion to the quantity of old seal fat put into the vat. Owing to its toughness, the latter does not yield to compression, nor does it give up its oil until decomposition sets in; and hence it does not, by this process, yield pale seal oil. As putrefaction proceeds, the color changes to straw; and, as the season advances, becomes every day darker, and a more nauseous odor is eliminated, until the brown oil at last runs out. As this running slackens, it becomes necessary to turn over what remains in the vats. The crib being generally divided into nine apartments, or *pounds*, this operation is performed by first emptying one of these, and dispersing the contents over the others, and then by filling and emptying them alternately, the entire residue—a complete mass of putrefaction—is turned over. By this means a further quantity of brown oil is obtained. The remains are then finally boiled in large iron pots, which during the whole season are in constant requisition for boiling the cuttings and clippings of the skin, and other parts of the pelts, which it is unadvisable to put into the vats. The produce of this, and the remains of the

pelts, are what is termed *boiled seal oil*. The refuse from the vats is found to be very valuable manure, and is readily purchased by the farmers in the neighborhood.

S. G. ARCHIBALD, of Newfoundland, has devoted much attention to the improvement of the method of extracting seal oil, and states that the different kinds of seals' fat, if taken while fresh, and subjected to a process of artificial heat, are capable of yielding not only a uniform quality of oil, but the oil so obtained is much better in quality than the best prepared by the old process, and free from the unpleasant smell common to all seal oil. He afterwards invented a steam apparatus for *rendering* seal and other oils, which is said to answer the purpose admirably.

Seal oil is used solely for illuminating purposes, and when tolerably pure, answers admirably, giving a beautiful, brilliant light, and producing no offensive smell, nor any clogging of the wick. Owing to the offensiveness it communicates to its salts, it is not applicable for the production of soap.

Porpoise Oil.—This, the produce of the *delphinus phocaena*, much resembles whale oil. It is liquid, and has a yellow color. When freshly extracted, it has a fishy smell, but by exposure to sun and air becomes nearly odorless. It then, however, acquires an acid reaction. It is soluble in about five parts of boiling absolute alcohol, but a portion of its solid constituent is deposited on cooling. By saponification it yields glycerin, with oleic, margaric, and phocenic acids.

Shark Oil.—This oil is procured from the liver of the basking shark—*squalus maximus*—of the bay of Galway, or sun-fish, as it is commonly called. The quantity of oil obtained from a single fish frequently amounts to one hundred and twenty gallons. It is light-yellow, of specific gravity 0.870 to 0.876, and retains its fluidity several degrees below the freezing point of water. It is said to give a brilliant flame, and without clogging the wick. RONALDS, who made a partial examination of it, reports that it consists of glycerin, a peculiar oleic acid, very rich in carbon, and another undefined liquid oil.

COD-LIVER OIL.—This oil is extracted from the liver of the common cod, and various other allied species of fish, but principally from the above—*gadus morrhua*—and the ling—*lota mola*. PENNANT describes the

method pursued in Newfoundland for its extraction as follows:—They take a half-tub, and, boring a hole through the bottom, press hard down into it a layer of spruce boughs, upon which they place the livers, and expose the whole apparatus to as sunny a place as possible. As the livers corrupt, the oil runs from them, and straining itself through the spruce boughs, is caught in a vessel set under the hole in the tub's bottom. According to Dr. DE JONGH, the usual mode of preparation in Norway is to store the livers in vats or tubs as soon as they are separated from the fish, where they are left until the end of the fishing season, when the oil that has separated is decanted, and forms the pale oil of commerce. The residue of the livers, being then submitted to heat, yields the darker oil. The best English oil, according to Dr. GARROD, is thus prepared:—The livers are collected daily, so that no trace of decomposition may have occurred, carefully examined, in order to remove all traces of blood and impurity, and to separate any inferior livers; they are then sliced and exposed to a temperature not exceeding 180°, until all the oil has drained from them. This is filtered, afterwards exposed to a temperature of about 50°, in order to congeal the bulk of the margarin, and again filtered and put into bottles well secured from the action of the air. In TAYLORS', every liver is opened, examined, washed free from blood, and, if sound and fit for use, is cut in pieces and put with others into a large pan with a portion of water. To the external surface of this pan steam is admitted, and the temperature being very carefully adjusted to about 180°, the livers are heated for a sufficient length of time to allow of the complete separation of the oil. The result of this process is the production of a sweet and nearly colorless oil, which is skimmed off and filtered through flannel. This, having been congealed for the separation of its margarin, is again filtered when required for use.

Three varieties of cod-liver oil are met with in the English market, and are known as the pale, the light-brown, and the dark-brown or black. The first is that extracted from the livers before putrefaction has commenced; the two latter have either remained longer in contact with the livers, have been prepared at high temperatures, or have been obtained from livers in a state of decomposition. Appended is Dr. DE JONGH's analysis of the three varieties:—

Of the three varieties of cod-liver oil, the most colorless, prepared entirely from fresh livers, is to be preferred, as it possesses the constituents of the oil in the purest state, and is, therefore, the most valuable as a therapeutic agent. From the investigation of several medical men, who have devoted much attention to the investigation of the therapeutic value of the several kinds of oils, the following may be gleaned in favor of the pale variety:—It is the real oil, as contained in the liver of the cod-fish—rich in biliary matters, and also in iodine and other inorganic principles; it contains no products of putrefaction, such as are found in the dark oils; it sits more easily on delicate stomachs; and experience has proved it to be a most effective therapeutic agent.

Adulteration.—Cod-liver oil is said to be extensively adulterated, and in some cases, indeed, an entire substitution is stated to be made, consisting of train oil, admixed with iodine, either in the free state, or as an alkaline iodide. This addition of iodine, or an iodide, may be readily detected by adding a solution of starch and a little sulphuric acid, when the blue iodide of starch is instantly developed.

Physiological Effects.—In the dose of a tablespoonful, cod-liver oil acts as a laxative, diaphoretic, and diuretic. The disagreeable flavor, especially of the dark-colored varieties, occasionally creates nausea and sickness, but when habit has surmounted the repugnance to it, these effects cease. In several cases it has proved an emenagogue, and on some occasions it has given rise to a cutaneous eruption. Dr. BARDSEY found that most persons were disposed to fatten under its use. According to Dr. THOMPSON and others, the olein is the active agent, while the presence or absence of iodine, bromine, *et cetera*, in the infinitely small proportions in which they are met with as constituents of the oil, cannot affect the results of its administration, and, in the opinion of Dr. WILLIAMS, cod-liver oil affords fat of a better kind, more fluid, less prone to change, and more capable of being absorbed into the structure of the body, than other forms of fat. Cod-liver oil has proved most useful in such cases as are of a gouty, rheumatic, scrofulous, or phthisical nature. But even in these it requires a long-continued use to prove successful. The oil is best adapted for relaxed, torpid, and phlegmatic temperaments, and for scrofulous subjects. The dose at the commencement for an adult is a tablespoonful, which has been sometimes increased to six times this quantity, and when given immediately after a farinaceous meal, and without any vehicle, rarely creates nausea or vomiting.—*Pereira*.

Sperm Oil.—This oil is obtained from the white whale—*physeter macrocephalus*. This, termed also the *cachalot* and sperm whale, is remarkable for the enormous size of its head, which is square, and apparently cut off in front. The animal is pursued chiefly for this oil, but it yields also *ambergris*. The oil is met with in several parts of the body, but the head is the principal receptacle of it. Here it is found in a large excavation of the upper jaw, anterior to, and quite distinct from, the true cranium which contains the brain. Like the fat of other animals, this oil is contained in cells, or cellular membrane; but besides these cells,

there are also ligamentous partitions going across, which serve as supports for the enormous quantity of oil of which the bulk of the head is principally made up. Sperm oil is extracted from the *case* by means of an opening made in the triangular-shaped cavity situated in the right side of the nose and the upper surface of the head, and the liquid contents are removed by a bucket. The dense mass of cellular tissue beneath the *case* and nostril, and which is technically called *junk*, also contains oil. Directly it leaves the skull of the animal, the oil begins to deposit large quantities of *spermaceti*, in the form of small crystalline laminae, from which the oil flows out by pressure, and is subsequently purified by the addition of a small quantity of solution of potassa, which precipitates certain matters by neutralizing the acid that held them in solution. Sperm oil is of a yellow color, has a slightly unpleasant smell, and is well suited for burning in lamps. It saponifies easily, and the soap obtained is brown, rather soft, and entirely soluble in water. According to HOFSTADTEN, it contains spermaceti, oleic, valerianic, and phytetoleic acids. The formula for the latter is $C_{32}H_{52}O_2$, HO. It is colorless, inodorous, melts at 86° , and solidifies at 82° . It does not yield sebatic acid by distillation, nor elaidic acid by the action of nitrous acid.

ADULTERATION OF OILS.—The enormous consumption of the various kinds of oils in the arts, manufactures, and other purposes, renders it a point of great importance to be able to detect the admixture of one oil with another of inferior quality, inasmuch as, owing to the physical similarity of the several varieties, great temptation exists for the commission of such frauds. The admixture of fish oil with animal or vegetal oils may be readily detected by the brown or black hue produced by the action of a stream of chlorine, and also, according to CALVERT, by the reddish coloration developed by boiling a mixture of the oil with solution of caustic soda. For the detection of a mixture of a siccative with a non-drying oil, several methods may be applied, as that of POUTET, which consists in the application of protonitrate of mercury, by which the non-drying oils yield elaidin; or that of BOUDET, which depends upon the same reaction, to produce which, however, nitrous acid is substituted for the mercury salt; and, in addition, the reaction discovered by MAUMÉNE, who showed that the non-drying oils give rise to a much higher temperature, when mixed with strong sulphuric acid, than is the case with those belonging to the class of siccatives. The fixed oils which may be solidified by BOUDET's method are those of sweet almonds, of filberts, and of colza; and of the drying oils, castor oil only is solidified by this treatment. One hundred parts of the oils mentioned, when treated by a mixture of nine parts of nitric acid with one of peroxide of nitrogen, require different lengths of time to become solid, as shown in the table subjoined:—

Oils.	Color developed by addition of the mixture.	Number of minutes required for congealing.	Proportion.
Olive oil,	Greenish-blue,	73	10-0
Sweet almond oil,	Dirty-white,	160	22-2
Oil of filberts,	Greenish-blue,	103	14-0
Oil of acajou,	Lemon-yellow,	40	6-0
Castor oil,	Golden-yellow,	603	82-6
Colza oil,	Yellowish-brown, ..	2400	328-0

HEIDENREICH determines the purity of the fixed oils, and the admixture of cheaper oils, approximately, as follows:—First, by observing the peculiar smell of the oil when gently heated in a small porcelain or platinum capsule, by means of a spirit lamp. The odor evolved will resemble that of the plant or animal from which it was obtained. This characteristic is said to be valuable if observed in conjunction with the genuine oil, and to furnish accurate indications of the presence of linseed, whale, train, or rape oils, in any mixture. The smell of the oil, however, as observed by PERROT, is not always a safe criterion, since an oil of the same fruit or nut has not always the same odor, but differs with the climate where produced, and the varied mode of extraction. HEIDENREICH further applies concentrated sulphuric acid, in the proportion of one or two parts per cent. of oil, and by this admixture a very intense action immediately ensues, the temperature rises, and the mixture becomes colored. A few drops of the oil are placed on a glass plate, having a sheet of white paper underneath; and to the oil is added a small drop of sulphuric acid, of specific gravity 1.632, when, according to the oil employed, a characteristic color will be developed without stirring. In the case of *rape oil*, a greenish-blue ring gradually forms at a certain distance from the acid; whilst towards the centre, where the action is more intense, light yellow-brown streaks may be observed. With *oil of black mustard*, the reaction much resembles that of rape oil, but is more violent. In *train oil*, a very peculiar

motion occurs, commencing at the centre, and extending to the outside; at the same time a red tint appears, which grows more and more vivid, until after ten or fifteen minutes the margin assumes a violet tinge, which, in about two hours, is uniform throughout. *Olive oil* instantly becomes pale yellow, and afterwards yellowish-green. In *poppy and sweet almond oils*, the color developed resembles that of the greenfinch, but afterwards becomes of a dead yellow hue. In *linseed oil*, a beautiful dark brownish red web is formed, gradually changing into brownish-black. Lastly, *tallow oil* is rendered brown.

If, in the process of HEIDENREICH, instead of the acid being allowed to act on the oil undisturbed, the two liquids are stirred together by means of a glass rod, the phenomena vary from those above described.

PERROT, reviewing the process of HEIDENREICH, directs twenty drops to be employed; and instead of the glass-plate and white paper, he uses capsules of white porcelain. In the place of sulphuric acid, he used also a saturated solution of bichromate of potassa in this acid, and in the proportion indicated above, namely, one drop to twenty of oil. In applying this method, it is always necessary, to insure greater certainty, to compare the effects upon the oil to be examined, with an oil the purity of which is undoubted. The appended table shows the reactions produced by sulphuric acid alone, and by the solution of bichromate in the acid:—

Oils.	Sulphuric Acid.		Solution of bichromate of potassa in sulphuric acid.
	Not stirred.	Stirred.	
Tallow oil,.....	Reddish spots with reddish circles.	Reddish-brown.	Reddish-brown.
Sweet almond oil,	Greenfinch yellow, with orange spots.	Dirty-green.	Yellowish small lumps.
Train oil,	Brown small lumps on a brown ground.	Lees of wine.	Brownish-red small lumps on a red ground.
Hemp-seed oil,	Reddish small lumps on a yellow ground.	Greenish-brown.	Yellow small lumps on a green ground.
Rape-seed oil,.....	Scarcely perceptible spots, or slight green coloration.	Green.	Yellow small lumps on a green ground.
Fish-liver oil,	Dark-red.	Dark-red.	Dark-red.
Linseed oil,.....	Reddish-brown.	Clotted on a grey or green ground.	Brown small lumps on a nearly colorless or slightly green ground.
Oil of madia sativa,	Slightly reddish-brown, underneath a film inclining to grey.	Olive-green.	Light-brown small lumps on an olive-colored ground.
Nut oil,	Yellowish-brown.	Clotted dark-brown.	Small brown lumps.
Olive oil,	Yellow, or orange-yellow.	Dirty-brown.	Brown.
Poppy oil,	Yellow, or greenish-yellow spots.	Olive or slightly green.	Small yellow lumps on a yellow or colorless ground.
Neat's-foot oil,.....	Yellow slight spots.	Dirty-brown.	Brown spots on a similar ground.
Castor oil,	Yellow slight spots.	Almost colorless.	Slightly green.

The action of the reagent upon the oil is not the same under all circumstances, but differs with the place of its growth, the manner of pressing, and its age. If, however, any oil be examined comparatively with a perfectly pure one, the proof of sophistication may be rendered pretty certain by observing the difference. After the discovery of fraudulent admixture, the oil is tested to ascertain the adulterant, either by reagents, or by the odor evolved when gently heated as before men-

tioned. This having been found out, small quantities of the suspected oil are added to a perfectly pure sample of the kind of oil under examination, and by this means the proportion of the mixed oils may be approximately estimated. Several cases of adulterated oils have lately been submitted to the Editor; and by carefully observing the reactions specified he has been able to state, to a certainty almost, the per-centage of foreign oil in each sample.

GENERAL TABLE OF REACTIONS.

Oils.	Caustic soda, spec. gravity 1.340.	Sulphuric acid, spec. gravity 1.845.	Sulphuric acid, spec. gravity 1.880.	Sulphuric acid, spec. gravity 1.885.	Nitric acid, spec. gravity 1.180. Another systematic method for testing the purity of oils, for which chemists are indebted to CALVERT, has been lately published, and goes far to solve this most intricate department of analytical chemistry. It consists in the employment of caustic alkali, and of various acids at different degrees of dilution, as well as mixtures of acids, and of acids and alkalies, successively applied. The preceding table, constructed by this chemist, indicates the reactions depended upon. The first test in the list is employed in the proportion of one volume of solution to five of oil, and is especially valuable to distinguish fish from other vegetal and animal oils. The test and oil are to be well mixed, and then heated to the point of ebullition. In the case of sulphuric acid, the same proportions as of caustic soda are employed in each case, and the mixture well agitated. With the acid, of specific gravity 1·475, the appearance is noted after standing fifteen minutes; with that of 1·530 after reposing five minutes; and with that having the density 1·635, after two minutes. With nitric acid, the mixture is made in a like proportion in each case, and the reaction noticed after five minutes. The caustic soda and nitric acid are applied together, by adding ten volumes of the former to five of the oil which has just been acted upon by one of nitric acid. The phosphoric acid is employed precisely as the other acids, and is extremely sensitive in the case of fish oils. The sulphuric and nitric acids are used in the proportion of one volume of a mixture of equal measures of acid with five of oil, and the appearance is observed after the lapse of two minutes. This test is especially applicable to the detection of oil of sesamum in admixture with other oils. Lastly, the aqua regia employed is composed of twenty-five volumes of hydrochloric acid, of specific gravity 1·655, and one of nitric acid, of specific gravity 1·330, and is allowed to remain at rest about five hours. The reactions given are those that ensue when a mixture of five volumes of oil with one of aqua regia is agitated, and allowed to stand five minutes. On the subsequent addition of caustic alkali to this mixture, a very vivid and distinct coloration is perceptible in many cases, and this, with the other appearances mentioned, render this last a most valuable agent for the detection of several instances of admixture.

STATISTICS.—Of the six principal vegetal oils, namely, palm, cocoa nut, castor, olive, linseed, and rape, the first four are imported in the state of oil only; the last two, chiefly as seed. The following table exhibits the proportions of the latter imported in the year 1850:—

	Linseed. Quarters.	Rapeseed. Quarters.
Russia,	482,813	3,235
Sweden,	870	—
Norway,	268	—
Denmark,	37	3,092
Prussia,	87,273	645
Hanse Towns,	1,153	2,872
Holland,	7,734	201
Naples,	1,476	—
Austrian territories,	40	2,480
Greece,	—	1,637
Wallachia and Moldavia, ..	910	1,280
Egypt,	17,517	—
East Indian empire,	26,144	13,126
Miscellaneous,	262	922
Total,	626,495	29,490

The quantity of the four principal vegetal oils imported in 1850 and the preceding two years, is shown by the following table:—

	Hundredweights		
	1848.	1849.	1850.
Palm oil,	510,218	493,331	448,589
Cocoa-nut oil,	85,463	64,452	98,040
Castor oil,	4,588	9,681	—
	Tuns.		
Olive oil,	10,086	16,964	20,783

The proportion in which these oils were furnished by various countries in 1849, was:—

	Palm oil. Hundredweights	Olive oil. Tuns.	Castor oil. Hundredweights.
Western Africa,	475,364	1	—
United States,	13,349	—	290
Naples and Sicily,	14	9,661	—
East Indies,	—	—	9,315
Canary Islands,	3,719	—	—
Malta,	—	2,237	—
Turkish Empire,	—	1,712	—
Tuscany,	—	832	—
Spain,	—	753	—
Brazil,	525	—	—
Ionian Islands,	—	506	—
Morocco,	—	368	—
Madeira,	353	—	—
Sardinia,	—	333	11
Miscellaneous,	7	461	65
Total,	493,331	16,864	9,681

The subjoined table exhibits the proportions of the several fixed oils and seeds entered in the port of Liverpool in 1849 and 1850, from the countries named:—

Oils.	Countries.	1849. Tuns.	1850. Tuns.
Poppy seed,	—	—	3
Ground nut,	—	80	90
Castor,	East and West Indies,	5	45
Castor seed,	Lisbon,	—	700
Rape,	Antwerp,	6	15
Rapeseed,	Antwerp,	3	5
Olive,	Manilla,	56	8
"	Barbary,	2,785	2,330
"	Malaga,	246	—
"	Levant,	1,243	2,100
"	Corfu,	280	762
"	Leghorn,	—	15
"	Palermo,	2,785	8
"	Gallipoli,	2,420	4,815

At the Great Exhibition a class of substances was exhibited, under the head of OILS, which are likely to prove of great commercial importance, as they possess properties differing from the finest vegetal oils; and some of them can, it appears, be supplied in large quantities, and at moderate cost. The jury, with a view to mark their appreciation of this class, awarded a prize medal to R. CLARENCE, Cape of Good Hope, for oil obtained from sheep's tails; and honorable mention to several exhibitors from the United States, for oil obtained from lard, by pressure, at a very low temperature. The collection of oils exhibited by the East India Company was very extensive, and contained a large number of highly interesting specimens.

In concluding this article, the Editor must express his thanks to his talented student, Mr. J. W. KYNASTON of Lincolnshire, for his very kind and valuable assistance

OPIUM—English, French, German, and Latin—is the inspissated juice of the head of the poppy—*Papaver somniferum*. The word is derived from the Arabic *afium*. The poppy is very extensively cultivated in Asiatic Turkey, Egypt, Persia, India, and occasionally in France, Germany, and England. The young plants are set in rows, about six inches asunder, and at first watered abundantly. When about six or eight inches high they are richly manured, and again abundantly irrigated as they are about to flower. When the seed vessels—Fig. 377—are nearly full-grown, the collection of the opium commences. For this purpose a body of women or children go over the fields about sunset, and make a number of parallel longitudinal incisions in each head, taking care not to

Fig. 377.

Fig. 378.

penetrate into the cavity where the seed is lodged. This is done with sharp shells, or preferably with a knife called a *nushtur*—Fig. 378—which consists of three or four blades tied together, so as to make fine parallel gashes, as shown in Fig. 377. Through these incisions the juice flows, and is scraped off and put into earthen pots, to be dried in the sun. To this is frequently added an inferior matter, obtained by subjecting the heads to pressure, and even by boiling the heads in water, and concentrating the extract. The greatest yield of good opium in India is stated at forty-one pounds per acre, and the average at from twenty to twenty-five pounds.

VARIETIES.—The quality of opium varies greatly, according to the country where it has grown, the species of poppy cultivated, the nature of the season, and the care taken in its collection and preservation. Some varieties are inferior to others, in the ratio of three to one. In the European markets the preference is given to the opium of Smyrna. This sort comes into the market in soft lumps, of greater or less bulk, the surface of which is covered with dock seeds, from the leaves in which they have been folded. It is light-colored internally, but the surfaces, when broken or cut, darken on exposure to the air. The smell is strong and peculiar, and the taste bitter and acrid. It contains ten to fourteen per cent. of morphin.

The opium of Constantinople is found in regular flat cakes or loaves, covered with poppy or tobacco leaves. It is drier than the Smyrna variety, and even brittle. In the hand it softens, and furnishes a fawn-colored paste, which turns brown on exposure to the air. It smells like the Smyrna opium, but fainter. Its yield of morphin is six or seven per cent.

The Egyptian or Alexandrian opium comes into the market in small, very dry, and very flat loaves, very clean at the surface, and showing scarcely a trace of the leaves in which they have been folded. Its color is dark-brown; its fracture clean and shining. It has a very feeble smell, and contains only three or four per cent. of morphin.

The opium of India is found in rounded masses of a darker hue, and more smooth and soft texture. It has an empyreumatic smell, and a less bitter but more nauseous taste. It is wholly soluble in water, and contains more or less sulphate of lime. Its per centage of morphin is two to five.

English and German opium resembles the East Indian in appearance, but is lighter in hue, and in quality equals the very best Smyrna. Opium collected in France has yielded sixteen to twenty-eight per cent. of morphia. The fickleness of the climate, and above all things the high price of labor, render it very improbable that opium can ever be advantageously cultivated in Western Europe.

PROPERTIES.—Genuine opium has a heavy narcotic smell, a very disagreeable bitter taste, with a warmish and subacid after-taste. It should be of a rich deep fawn color, or brown, of a tough plastic consistency, and a smooth uniform texture, marking paper with an interrupted streak. Its specific gravity is 1.336, which is one of the proofs of its purity, as few vegetal substances are so heavy, except gum-arabic and opoponax. Bad opium wants the peculiar narcotic odor; it is friable or soft, full of dark-brown or black patches, or is all of a deep black, marks with a continuous brown streak, tinges water yellow, easily melts when exposed to heat, and tastes sweetish.

Opium is soluble in water, alcohol, and ether, and more readily in proof spirit. It also dissolves in acetic, citric, or any of the vegetal acids in solution. Boiling water dissolves about forty-one per cent., holds fifty per cent. in solution, and leaves the remaining nine untouched.

Opium is of an exceedingly complicated nature. Besides moisture, gum, caoutchouc, lignin, and bassorin, it contains at least thirteen or fourteen distinct principles, most of which occur in no other substance. Of these, nine are of a basic or alkaline nature—morphin, codein, narcotin, narcein, paramorphin, papaverin, opianin, narcogenin, and pseudomorphin; two are neutral, meconin and porphyroxin; whilst four, meconic acid, a brown extractive matter, a resin, and a fixed oil, possess acid properties; and an essential or volatile oil is too little known to admit of classification.

These substances occur in varying proportions, some of them in very minute traces, whilst others are in many samples entirely wanting. It is still doubtful whether all actually exist as such in crude opium, or whether some of them are not *alteration products*, formed by the influence of the reagents used to effect their extraction. It is also questionable, as far at least as the basic constituents of opium are concerned, whether they are totally distinct and unconnected principles, or merely successive modifications of one or two bodies.

PROXIMATE PRINCIPLES.—The Editor will next pass to a description of the various constituents of opium, with their methods of extraction.

Morphin.—This, the most important constituent of opium, was discovered in 1816 by SERTUERNER. Its composition is indicated by the formula $C_{20}H_{20}N_2O_6$, and its symbol is M. It crystallizes in four-sided prisms of an adamantine lustre, containing two equivalents,

or 5.73 per cent. of water, which is expelled at 248°. At higher temperatures it fuses into a yellow liquid, and is subsequently decomposed.

This alkaloid is inodorous, strongly bitter, insoluble in cold water. It dissolves in ninety-two parts of boiling water, and is again deposited in crystals as the solution cools. It dissolves in forty parts of anhydrous alcohol, and in about thirty of proof spirit at a boiling temperature. It is sparingly soluble in ether, but readily in the fatty and essential oils. It dissolves in the fixed caustic alkalies, and to a small extent in ammonia. In nitric acid it dissolves with a blood-red color. Morphin ranks amongst the more powerful bases; its solutions redden turmeric paper, and turn violet paper green. If thrown in powder into a saturated solution of the sesquisulphate of iron, as nearly neutral as possible, it strikes a blue color. The sulphate of this base is formed whilst the iron, reduced from sesquioxide to protoxide, combines with *morphic acid*, a product of the decomposition of a part of the morphin. Morphin decomposes iodic acid in solution, setting the iodine free, whilst the other organic ingredients combine with the acid to form iodates. This reaction is, therefore, used for the detection of morphin. The solution in question is rubbed in a mortar with a little mucilage of starch. A few drops of iodic acid, or of a dilute solution of the perchloride of iodine, are then added. The blue tint which iodine forms with starch is, in this case, a proof of the presence of the alkaloid.

Where alcohol is dear, the process of GREGORY and ROBERTSON will be found preferable. These chemists extract a known weight of opium in cold water, and evaporate to the consistence of sirup. It is then redissolved in water, and again concentrated. To the boiling liquid dry chloride of calcium is added, in the proportion of nearly one-fourth of the opium employed. The chloride of calcium must be perfectly free from iron, otherwise the deep-red meconate of iron will be produced, and greatly impede the purification. The hot liquid is now mixed with cold water, which throws down meconate and sulphate of lime, coloring matter, resin, and the volatile oil of opium.

The precipitate is filtered off, and the clear liquid concentrated, when a fresh deposit of meconate of lime will be formed. Filter again, wash the precipitate on the filter with a little cold water, and add the washings to the filtrate. This is now evaporated down to the consistence of sirup, and allowed to stand for some days. There is then obtained a crystalline mass—a double salt of morphin and codein—and a dark mother-liquor, containing an acid meconate of lime, a little morphin, and the narcein, meconin, narcotin, and paramorphin.

The crystalline mass is drained, pressed between sheets of bibulous paper, redissolved in water, acidulated with a very little hydrochloric acid, and evaporated to crystallization. The mother-liquor, on concentration, generally yields a further deposit. The crystals are redissolved in hot water, the solution neutralized with a little chalk, and treated with animal charcoal. The amount of water must be enough to retain the salt in solution on cooling, and the temperature must not exceed 190°. After twenty-four hours the solution is

filtered, and a few drops of acid added, which favors the crystallization. The crystals are redissolved and again crystallized, pressed between bibulous paper and dried in the stove. The mother-liquor is treated in the same manner with chalk and charcoal.

The salt obtained in this manner is a double one, free from narcotin. It is dissolved in water, boiled, and treated with ammonia, which precipitates the morphin. This is filtered off, washed with a little cold water, and dried. From the filtrate codein is obtained.

Morphin is often contaminated with narcotin, which may be entirely removed by ether, or the impure mass may be treated with very dilute acetic acid which dissolves the former, leaving the latter untouched. To determine the purity—from narcotin—of any sample of morphin, it may be dissolved in hydrochloric acid, and treated with caustic potassa in excess, in which the morphin will entirely dissolve, while any narcotin present remains untouched. If a very small portion of morphin is placed in a watch-glass with a little pure sulphuric acid and an equal quantity of water, and if a particle of bichromate of potassa be added, a nickel green color appears, which changes, first to a copper green, and finally, to a dark dirty green.

The salts of morphia are mostly crystalline, bitter, very soluble in alcohol, but insoluble in ether. They are precipitated from their solutions by alkaline carbonates; caustic alkalies added in excess redissolve the precipitates. They are thrown down by infusion of gall nuts; they strike a blue color with the neutral sesquisalts of iron, and decompose iodic acid in the same manner as free morphin. Terchloride of gold precipitates the salts of morphin with a yellow color, which changes to blue. Nitrate of silver communicates to them a blackish-grey color, and is gradually reduced.

Codein was discovered by ROBIQUET in 1833. The anhydrous substance consists of $C_{35}H_{20}NO_5$. ANDERSON and REGNAULT give the formula $C_{38}H_{21}NO_6$. By solution in water, or in aqueous ether, it is obtained in crystals often of considerable size, belonging to the right prismatic system, but presenting a considerable number of modifications. These crystals contain two equivalents, or 5.67 per cent. of water, which they lose at elevated temperatures, and at 302° fuse without decomposition or volatilization. One hundred parts of water at 60° dissolve 1.26 of codein, at 110°, 3.7, and at 212°, 5.9 parts. If more codein is present than boiling water can dissolve, the undissolved portion fuses and forms a kind of oily layer at the bottom of the vessel. It dissolves in alcohol, more readily when hot than when cold, and is taken up very freely by ether. It is insoluble in very highly concentrated solutions of potassa, which, joined to its behavior with ether, distinguishes it from morphin.

Codein is a very powerful base; it turns red litmus paper blue, and precipitates the oxides of lead, iron, cobalt, and nickel from their solutions. It is precipitated from the solutions of its salts by potassa and by ammonia; in the latter case, however, it does not fall immediately, but is slowly deposited as small transparent crystals.

Codein is obtained from the last filtrate in GREGORY and ROBERTSON'S process for preparing morphin. As

the codein forms only from one-sixteenth to one-thirtieth of the morphin, it is of course mixed in this fluid with a corresponding amount of chloride of ammonia, which must first be decomposed by potassa. Much advantage is gained by first evaporating the liquid to crystallization, and pressing the crystals first deposited: as, however, they are but little less soluble than chloride of ammonia, this process must not be carried too far, or much of the codein will be wasted. The crystals so obtained are dissolved in boiling water, and a highly concentrated solution of caustic potassa is added in excess. Codein is in part precipitated as an oily liquid, which gradually concretes into a solid mass, and in part deposited as crystals when the liquid cools. By evaporating the fluid another crop of crystals is obtained, and finally, when the mother-liquor has been very highly concentrated, it is filled, on cooling, with morphin in long silky crystalline needles.

The crystals of codein thus obtained are dissolved in hydrochloric acid, boiled with animal charcoal, and reprecipitated with a slight excess of potassa. The precipitate is finally dissolved in ether, which ought to be free from alcohol, and allowed to crystallize.

The salts of codein are for the most part soluble and crystalline. Their solutions give with bichloride of platinum a pale-yellow pulverulent precipitate; with chloride of mercury a white precipitate, soluble in boiling water and alcohol; and with chloride of palladium, a yellow precipitate, which is decomposed on boiling, with separation of the metal.

Narcotin consists of $C_{40} H_{25} NO_{14}$. It is a white inodorous substance, forming prismatic crystals, which fuse at 338° , and solidify at 266° , the solidification being attended with a loss of weight amounting to three or four per cent. If it is cooled slowly, several centres of crystallization form at its surface and gradually increase in size. It is insoluble in cold, and requires five hundred parts of boiling water for solution. It dissolves in one hundred parts of seething alcohol, but is taken up more readily by this menstruum at the boiling point. It is very soluble in ether, in the fatty and the essential oils.

Narcotin is without action on the sesquisalts of iron, on iodic acid, and the terchloride of gold. Nitric acid colors narcotin an orange-red. In sulphuric acid, containing about one-thousandth of nitric acid, the liquid assumes in the course of seven or eight minutes an intense blood-red color, which the addition of more nitric acid destroys. Peroxide of nitrogen acts so energetically upon narcotin, that, if the quantity be not very small, ignition ensues in a few seconds.

To prepare narcotin, the grounds left after the extraction of opium by water are boiled with dilute acetic acid, the liquid is strained and filtered, and the clear liquid is precipitated by ammonia. The precipitate is then redissolved in strong boiling alcohol, along with a little animal charcoal. The solution is filtered whilst boiling, and, as it cools, narcotin is deposited in crystals.

Narcotin combines with the more powerful acids, forming salts which are intensely bitter. They are thrown down from their solutions by infusion of gail-nuts, and by the caustic alkalies; but the precipitate caused by the latter does not redissolve in excess.

Narcein— $C_{40} H_{29} NO_{18}$ —is extracted from the dark-brown mother-liquor obtained in the preparation of morphin. It is sparingly soluble in water, insoluble in ether, but very soluble in alcohol. It forms fine silky crystals, which have a metallic taste. It dissolves in dilute acids, but without neutralizing them, and the solutions on evaporation deposit narcein unaltered. It is colored blue by strong acids and by chloride of calcium, but not by sesquisalts of iron.

Paramorphin or *thebain*—was discovered by THIBOUMERY, and was examined by KANE, who assigns to it the formula $C_{38} H_{31} NO_6$. Paramorphin is strongly analogous to narcotin; but it crystallizes in short needles, fuses at a much lower temperature— 266° —is much more readily soluble in alcohol, and its taste is acrid rather than bitter. It has an alkaline reaction, and combines with acids, forming crystalline salts. It is obtained by extracting opium with excess of lime, treating the residue with a dilute acid, and precipitating with ammonia. The powder is treated by alcohol, which, on evaporation, leaves paramorphin in crystals.

Papaverin was first obtained by MERCK. It has the formula $C_{40} H_{21} NO_6$. It is insoluble in water, and sparingly soluble in cold alcohol and ether, but dissolves more freely on the application of heat, and is deposited in irregularly agglomerated, colorless, prismatic crystals. When moistened with concentrated sulphuric acid it acquires a deep-blue color. When treated with moderately strong nitric acid it is converted into a yellow crystalline mass. It restores the blue color of reddened litmus, and neutralizes acids, forming crystalline salts.

It is obtained by precipitating the aqueous extract of opium with soda, exhausting the precipitate with alcohol, and evaporating the brown tincture thus obtained to dryness. The dry resinous residue is dissolved in dilute acid, the liquid filtered and precipitated by ammonia, when a resinous matter is obtained which contains the papaverin. This is then redissolved in dilute hydrochloric acid, and precipitated with acetate of potassa. The precipitate is washed with water, and treated with boiling ether, from which, on cooling, the papaverin is deposited in crystals.

Opiatin was discovered in Egyptian opium by HINTERBERGER. Its constitution is represented by $C_{42} H_{21} NO_{14}$. It was at first mistaken for narcotin. Opiatin crystallizes in long colorless, transparent, diamond-like needles, of the prismatic system. It is inodorous, insoluble in water, and but sparingly soluble in boiling alcohol, from which, on cooling, it completely separates. The solution has a powerful and persistent bitter taste, suffers no alteration at the temperature of the water bath, and has a decided alkaline reaction. It is not affected by concentrated sulphuric acid, but dissolves in nitric acid with a yellow color. Sulphuric acid, to which nitric acid has been added, gives a blood-red tint, which after a short time passes into a straw-yellow. Opiatin forms salts with the acids, and crystalline double compounds with the chlorides of platinum and mercury. From the solutions of its salts it is thrown down in white flakes. It was obtained by extracting the opium with water, adding ammonia to the solution, washing the precipitate obtained, first with water

and then with alcohol, and drying. It is now dissolved in alcohol, deodorized with animal charcoal, and separated from morphin by repeated crystallizations out of alcohol.

Narcogenin has been separated by BLYTH, and found to consist of $C_{36}H_{18}NO_{10}$.

Along with narcotin, to which, when perfectly freed from other compounds, BLYTH assigns the formula $C_{46}H_{25}N O_{14}$, WERTHEIM has discovered two other homologous bodies.

Pseudomorphin has been found in a few samples of opium by PELLETIER, according to the analysis of which it consists of $C_{27}H_{18}N O_{14}$. It forms shining scales sparingly soluble in water, insoluble in alcohol and ether, but soluble in alkalies. Like morphin it is colored blue by sesquisalts of iron. It dissolves in hydrochloric and acetic acids, but its salts have not been fully examined.

Porphyroxin or *opin*, is a neutral body, which crystallizes in colorless minute shining needles. When heated it melts, becomes resinous and friable. It is colored of an olive-green by strong nitric or sulphuric acids, and is dissolved by dilute hydrochloric acid, the solution turning red when boiled or allowed to stand. The acid solution is decolorized by alkalies, and yields with terechloride of gold a dirty-red precipitate, a rose-colored one with acetate of lead, and a brown with protochloride of iron. The solution is not changed by chlorine water, and takes a characteristic red tint. It is probably identical with sanguinarin and cholerythrin. Porphyroxin is prepared by taking the ethereal extract which, after exhaustion with water, remains from the preparation of meconin, and treating with boiling alcohol as long as anything is taken up. The crystalline mass which separates on cooling and evaporation is dried, dissolved in boiling alcohol, and treated with ammonia in excess. The precipitate formed is dissolved in hydrochloric acid, evaporated to a sirup, freed from any crystals that may separate, the liquid again precipitated with excess of ammonia, and the deposit taken up in boiling alcohol, when, on evaporation, porphyroxin separates in minute crystalline needles.

Meconin is a neutral, non-nitrogenous body, which does not form salts. It is prepared by exhausting powdered Smyrna opium with boiling ether. The residue, after distilling off the ether, is repeatedly boiled with water, the solution evaporated, the residue dissolved in ether, decolorized with animal charcoal, evaporated, and the meconin obtained recrystallized from water.

Meconic acid is best obtained in a state of purity by dissolving the pure meconate of potassa in eighteen parts of hot water, and adding two or three parts of concentrated hydrochloric acid. As the liquid cools crystals are deposited, which are redissolved in water, again treated with hydrochloric acid, and thus obtained entirely free from potassa. It should not be boiled in presence of any acid, as it is thus converted into komenic acid.

Meconic acid forms beautiful pearly crystalline scales, of a harsh sour taste, sparingly soluble in cold, but more readily in hot water and in alcohol. The anhydrous acid consists of $C_{14}HO_{11}$, and is denoted by the symbol Me; the acid dried at 212° contains in addi-

tion three, and the crystalline acid nine equivalents of water.

By prolonged boiling in water the acid is decomposed, yielding komenic, oxalic, and carbonic acids, besides a deep dusky-yellow coloring matter. Sulphuric and hydrochloric acids at 212° convert meconic acid into carbonic and komenic acids. The same products, with the addition of water, are obtained on exposing meconic acid to a temperature of 248° ; but at greater heats the komenic acid is again resolved into pyromeconic and carbonic acids. Caustic potassa or soda in excess converts meconic acid into oxalic and carbonic acids, and a brown matter not perfectly known. Charcoal readily absorbs meconic acid, and cannot, therefore, be used in its purification. Meconic acid and all its soluble salts give an intense blood-red color with the sesquisalts of iron, a reaction often employed for the detection of small traces of opium. It should be borne in mind that a very similar reaction with sesquisalts of iron is produced by indigotic acid and the alkaline indigotates, as well as by hydrosulphocyanic acid and the soluble sulphocyanides.

Meconic acid forms three classes of salts, containing respectively one, two, or three equivalents of base.

The bibasic meconate of potassa—Me, 2 KO HO—is obtained by adding a solution of caustic potassa to the crude meconic acid, obtained from the meconate of lime, till a greenish tinge begins to appear. A gentle heat is applied till the whole is dissolved. As the liquid cools, the impure salt crystallizes out in large quantities. This is purified by pressure between folds of bibulous paper, and repeatedly crystallized. This salt, which is used for the preparation of the pure acid, is sparingly soluble in cold water. The monobasic salt—Me KO, 2 HO—is formed by the cautious addition of hydrochloric acid; and the tribasic—Me 3 KO—by the addition of a proper quantity of caustic potassa. This salt is yellow and soluble.

Meconate of lime, an insoluble bibasic salt, is obtained by adding a solution of chloride of calcium to the infusion of opium, as in the process of GREGORY and ROBERTSON for preparing morphin. For the preparation of meconic acid, one part of this salt is mixed with twenty parts of boiling water and three parts of concentrated hydrochloric acid. As the solution cools, a monobasic salt—Me Ca O, 2 HO + aq—is deposited in silvery crystals. These are strained off, dried, and again treated in the same manner, avoiding a boiling temperature, till a crystal, heated upon platinum foil, leaves no residue of lime. The crude acid thus obtained is converted into meconate of potassa and purified, as stated above.

Meconate of sesquioxide of iron is a very soluble salt, of a blood-red color, which is decolorised by sulphurous acid and protochloride of tin.

The brown extractive acid requires further investigation. It is probably a mixture of different matters, and, perhaps, a product of alteration.

The resinous matter of opium contains nitrogen. It is brown, without smell or taste, insoluble in water and ether, but soluble in alcohol. It is softened by heat, and dissolves in alkalies. The oily matter has usually a yellow or brownish tinge, due probably to impurities.

It is acid and saponifiable. The essential oil has not yet been obtained in a state of purity.

The lignin, bassorin, gum, and caoutchouc require no remarks.

ESTIMATION.—Opium is most extensively adulterated, *perfectly genuine samples* being in fact very rare. The drug of commerce contains water, clay, sand, gravel, sulphate of lime, pieces of lead, dung of sheep and oxen, extracts of liquorice, of belladonna, of hemlock, celandin, and lettuce, of *glaucium luteum*, bruised grapes freed from their stones, poppy stalks and husks, previously beaten up with white of egg, aloes, gum-arabic, and tragacanth. Sometimes also the grounds of opium, from which the morphin has been extracted, are sold as the entire drug.

The amount of water may be ascertained by drying a weighed portion in the steam bath, and noting the loss. Mineral adulterations may be detected by incinerating a known quantity of the drug, and weighing and examining the residue.

Generally speaking, however, the only satisfactory method of testing opium is to determine the quantity of morphin which it contains.

For this purpose GUILLIERMONT recommends to take two hundred grains of the sample to be tested, cut it in slices, and rub it well in a mortar with four times its weight of alcohol, strain it through linen, squeeze the residue, and pour upon it three hundred grains more alcohol; mix the strained liquors together in a wide-mouthed flask, and add about sixty grains of ammonia. In twelve hours the morphin will be spontaneously separated in crystals. These are thrown upon a filter, washed with a little water to remove meconate of ammonia, and afterwards shaken in ether, or preferably in chloroform, which dissolves out the narcotin, and leaves the morphin in a state of purity. It is now carefully dried and weighed.

THIBOUMERY extracts the weighed sample of opium repeatedly with water, filters the liquors, mixes, evaporates to a thick sirup, and redissolves in water. A large excess of ammonia is added to the boiling solution, which is allowed to cool, and then filtered. The precipitate collected on the filter is now thoroughly washed with cold water, and dried. It is next boiled in alcohol, specific gravity 0.84, and acetic acid is added drop by drop until the liquid turns red. It is now filtered, and the filtrate is again precipitated with ammonia. The precipitate is pure morphin.

To detect minute quantities of opium, if mixed with other substances, the body to be tested is treated with a little potassa, and well shaken with ether. A piece of bibulous paper is dipped several times in the ethereal solution, and allowed to dry between each immersion. It is then moistened with dilute hydrochloric acid, and exposed to the steam of boiling water, when it acquires a red color, more or less intense, according to the quantity of opium present.

PHYSIOLOGICAL EFFECTS.—Opium is used medicinally as a narcotic, sedative, and anodyne, but it usually acts first as a stimulant, and the sedative and narcotic effects are apparently the subsequent collapse of the system. When it excites, the first symptoms are heat, thirst, absence of mind, and sometimes headache and

vertigo, afterwards exhilaration of mind, which ends in sleep, attended often by the most wonderful and agreeable dreams. On awaking, languor and nausea succeed. In Turkey, Persia, and China it is generally employed as a source of pleasurable excitement, and even in this country the habit of opium-eating appears to be on the increase. The habitual indulgence in this drug brings on the most abject debility and prostration of mind and body. In large doses it produces giddiness, stupor, delirium, convulsions, and death. Upon the lower animals, opium and its various preparations have a less marked action than upon man. Thus an ape has been known to take five hundred grains of morphin in a month, or nearly seventeen grains per day, while one-eighth of a grain is as much as can be safely administered to a man in a single dose. To young children opium, in every form, is peculiarly injurious.

It is far from being thoroughly ascertained upon which of the constituents of opium its physiological action principally depends. Morphin is powerfully narcotic and sedative, but does not appear to produce the excitement derived from the use of natural opium. Codein is said by some to produce a calm and gentle sleep, which does not leave behind the dull headache that generally follows after the use of morphin. Others state that it causes violent excitement and intoxication. Narcotin is generally considered inert, though MAJENDIE maintains that it is very active when dissolved in oil. Meconic acid and the soluble meconates were at one time considered to be the active ingredient of the Manna of St. Nicholas, used as a slow poison in the middle ages; but this view is not supported by more recent observations.

In cases of poisoning with opium, or its alkaloids, the peculiar nature of the symptoms observed before death will generally lead inquiry in the right direction. If evidence on this head is wanting, it is necessary to shred the stomach, intestines, liver, *et cetera*, with their contents, and add to every one hundred parts, twelve parts of anhydrous lime or baryta; pound the whole well in a mortar; heat to 212°, and pulverize the mass most thoroughly. The powder is now three times exhausted with boiling absolute alcohol, and the liquid filtered after cooling. The bodies sought for are thus obtained, contaminated merely with fatty or resinous matters. Evaporate now carefully to dryness, and treat the dry residue with ether, to remove fatty matters. Morphin, if present, will remain undissolved, and may be filtered off and recognized by the usual tests. Codein, narcotin, and papaverin will be dissolved by the ether; add acetic acid, and precipitate with ammonia.

OXALIC ACID.—*Acide oxalique, Acide carbonéux, French; Kleesiure, Oxalsiure, German.*—This acid was obtained by SAVARY, 1773, and WIEGLER, 1779, from the salt of sorrel or binoxalate of potassa, and by BERGMANN from the action of nitric acid upon sugar, but its constitution was first pointed out by SCHEELÉ.

It exists naturally, combined with potassa, soda, or lime, in a great variety of plants, especially *oxalis acetosella* and *corniculata*, *Rumex acetosella* and *acetosa*, also in guano, in certain urinary sediments and calculi,

and combined with protoxide of iron, *Humboldtite*, in beds of brown coal.

It is generated by the action of nitric acid upon vegetal matter, especially upon substances containing no nitrogen—such as starch, gum, lignin, washed sawdust, and most advantageously, sugar or treacle. It is formed also when cyanogen is decomposed by water, or uric acid by chlorine, or the peroxides of lead and manganese; when organic substances are treated with caustic alkali in large excess; and during the preparation of potassium from carbonate of potassa and charcoal.

PROPERTIES.—Oxalic acid, in its ordinary crystalline state, forms large transparent colorless prisms belonging to the oblique system; specific gravity 1.641; inodorous, but intensely sour. It dissolves, if pure, in eight parts of water at 60°, but in two parts if contaminated with nitric acid. Boiling water dissolves its own weight. The crystals usually give out a sharp crackling sound during solution. It dissolves also in four parts of alcohol, and in sulphuric and hydrochloric acids, without decomposition, at ordinary temperatures.

The crystals, if heated in the air, lose two equivalents of water, and form a white, effloresced, powdery mass, which, at about 200°, sublimes, and is deposited upon cold surfaces as transparent, colorless, hard, slender needles. The so-called dry oxalic acid is composed of C_2O_3 , $HO = 45$. Some chemists are of the opinion that its equivalent ought to be doubled, thus: $C_4H_2O_8$ or $C_4O_6 + 2HO = 90$. The radical theory assumes the existence of a hypothetical anhydrous acid, $C_2O_3 = 36$, of which the ordinary dry acid is then regarded as a hydrate, HO, C_2O_3 . Oxalic acid is sometimes represented in chemical formulæ by the symbol, O or Ox .

This is one of the most powerful acids. When dissolved in two thousand parts of water it still reddens litmus. At boiling temperatures, in the moist way, it expels most other acids from their combinations; a fact which depends in part on its fixity, and in part on the insolubility of most of its salts. Thus it decomposes not only carbonates, nitrates, chlorides, but chromates, phosphates, and even some sulphates and fluorides.

Oxalic acid is decomposed if passed through a red hot tube, if treated with chlorine or bromine gas, or if heated with nitric, iodic, sulphuric, phosphoric, chromic, and vanadic acids, or if treated with the peroxides of lead and manganese. In contact with the chlorides of gold and platinum, it is decomposed under the influence of light, the metal being precipitated, and carbonic acid gas evolved. The reaction with salts of gold may be advantageously applied for estimating the amount of oxalic acid present in any of its compounds. The substance in question is dissolved in water if practicable, otherwise in a little hydrochloric acid, and water added in excess. A solution of the auro-chloride of sodium is then added, the liquid boiled for some time, solar light being excluded, the precipitate of reduced metallic gold is allowed to subside, filtered off, washed, dried, ignited, and weighed. One equivalent of gold represents three equivalents of oxalic acid.

MANUFACTURE.—The manufacture of oxalic acid is very simple. Brown sugar or treacle is submitted to the action of nitric acid. The starch-sugar obtained from potatoes or horse chestnuts may be likewise employed.

For this purpose clean potatoes or horse chestnuts, the latter previously freed from their husks, are ground to a pulp, which is then repeatedly washed with water. The mass thus purified is mixed with sulphuric acid to the extent of about two per cent. of the original weight of the potatoes, and a sufficient quantity of water to reduce it to a tolerably fluid pulp. The whole is then run into a leaden tank, and boiled by means of steam pipes passing through the vessel. This operation is continued for some hours until a drop of the liquid, when taken out, is no longer turned of a bluish color on the addition of iodine. The whole is then strained through a horse-hair cloth, and the clear liquid evaporated down at a steam heat, until it has a specific gravity of 1.75, or until a gallon weighs about fourteen pounds. It is now ready for use.

In the conversion of sugar or sirup into oxalic acid, one may use either vessels of earthenware or wooden tanks lined with lead. The former are generally made to hold about two gallons each, and are set in large numbers in a stout water-bath built of brickwork, which is lined with lead or cement, and heated by coils of steam-piping. The wooden tanks are generally about eight feet square by three feet deep, each being heated by about forty-eight feet of one-inch steam-pipe. They should be provided with large taps placed at the bottom to draw off the liquor into the crystallizing pans.

The vessels are now charged with the sugar or sirup, and nitric acid is added. The usual proportions are—to every hundredweight of sugar as much nitric acid as can be obtained from five hundredweight of nitrate of potassa, and two and a half or about three hundredweight of sulphuric acid. The nitric acid should have a specific gravity of from 1.200 to 1.270. If a more concentrated acid is employed great loss is occasioned, since a large part of the sugar is then converted, not into oxalic, but into carbonic acid. The tanks are then heated to about 125°. If the operation is properly managed, there will be a moderate, steady, disengagement of gas, and a very faint smell of nitric oxide, but no appearance of orange fumes. A slight addition of sulphuric acid is generally considered advantageous. When the operation is at an end, the liquid is let off into shallow cooling tanks, which are also made of wood, and lined with lead, and is there allowed to crystallize. The mother liquor is run off from the crystals, and added to the materials in the next operation. The crystals are carefully drained, washed, dried in a stove, and, if necessary, redissolved and recrystallized. The yield is variously stated; one hundredweight of good brown sugar affording, according to some, fifty to sixty pounds; according to others, one hundred and forty pounds of acid. If, however, the process is properly conducted, and the crystals freed from moisture and nitric acid, the result will be about one hundred and twenty-five pounds. Treacle, if of good quality, gives about one hundred and six pounds per hundredweight.

OXALATES.—The salts of oxalic acid are either *normal*, of the composition, C_2O_4M —where M represents any metal—*acid*, C_2O_4M , C_2O_4H , *hyperacid*, C_2O_4M , $3C_2O_4H$, or *basic*. Alkaline normal oxalates are reduced

on ignition out of contact with the atmosphere to carbonates, carbonic oxide gas being evolved. Oxalates of the heavy metals yield either pure metal and carbonic acid gas—copper, mercury, platinum, silver—or oxide, and a mixture of carbonic acid and carbonic oxide gases—iron, manganese, *et cetera*. Most normal oxalates are insoluble in water, but dissolve in dilute nitric acid.

The most important of the salts of oxalic acid are the oxalate of ammonia—formed by neutralizing ammonia or its carbonate with oxalic acid—and the acid oxalate of potassa—*salt of sorrel* or *sal acetoselleæ*— $C_2O_4K + C_2O_4H + 2Aq$. The former is used in the laboratory for detecting and determining lime; the latter is prepared by neutralizing a given quantity of oxalic acid with carbonate of potassa, and then adding as much more acid, or by pressing the leaves and stalks of the *oxalis* species, concentrating the clarified juice to crystallization, and recrystallizing so as to get rid of impurities. It forms oblique prismatic crystals, which are persistent in the air, and soluble in fourteen parts of boiling water. This salt is employed for the same purposes as the free acid. A hyperacid salt, or quadroxalate, of the constitution $C_2O_4K, 3C_2O_4H$, is sometimes found in the market along with, or instead of, the preceding.

Oxalate of lime is a white powder, formed whenever oxalic acid, or one of its soluble salts, is added to a calcareous solution. It is also found in a crystallized state in animal and vegetal tissues. It is insoluble in water, solution of chloride of ammonia, or acetic acid, but dissolves readily in dilute nitric or hydrochloric acid, and is decomposed on prolonged boiling with soluble salts of lead, copper, silver, cadmium, zinc, nickel, cobalt, strontia, or baryta.

ESTIMATION.—Oxalic acid may be very readily detected by adding to its solution, which, if acid should be previously neutralized with ammonia, a solution of sulphate of lime. A white cloud is produced in a few minutes.

The amount of oxalic acid in any substance may be determined either by the process with one of the salts of gold as described above, or from the carbonic acid given off on decomposition of the oxalic acid in contact with sulphuric acid and peroxide of manganese. A weighed portion of the oxalate to be examined, or of the free acid, which must be subsequently dissolved in water, and slightly supersaturated with ammonia, is placed in the larger flask of FRESSENIUS and WILLS' alkalimetric apparatus, along with an excess of finely-powdered peroxide of manganese, freed previously from carbonates by lixiviation with dilute hydrochloric acid. Water is added until one-third of the flask is filled. The other flask is then charged with sulphuric acid, and the operation is conducted exactly as in the examination of a sample of alkali. When the process is at an end, which is shown by a total cessation of the evolution of gas, even though a fresh portion of sulphuric acid is sucked over, the apparatus is weighed, and the loss determined. Every twenty-two grains of carbonic acid lost, represent twenty-three grains of oxalic acid present in the sample. This method is capable of great precision, but requires, of course, a sensitive balance.

PATENTS.—A great object with manufacturers of oxalic acid is to economize nitric acid, by reoxidizing the nitric oxide given off in the process. To this the carbonic acid, which is always simultaneously generated, proves an obstacle. JULLION's method, patented in 1846, is as follows:—The materials are placed in a so called *generating vessel*, holding about a hundred gallons. This vessel resembles a Woulfe's bottle, provided with a movable top fitting air-tight. It is heated by a water bath, or a steam jacket. The nitric acid is then introduced, and a current of air, or of oxygen gas, driven in through a pipe passing through one of the apertures in the top. The nitric oxide given off by coming in contact with the oxygen is partly converted into nitrous acid and peroxide of nitrogen, which are reabsorbed by the liquid in the generating vessel. The rest is led off by a pipe issuing from another hole in the top, which traverses a furnace where it is enlarged, and heated to 600°–900°. Here it is charged with spongy platinum, in contact with which all the lower oxides of nitrogen are converted into nitric acid, which is then condensed in the usual manner.

In CRANE and JULLION's *continuous process*, a covered vessel constructed of slate, and termed a *generator* is charged with mother liquor from a former operation. Above the generator are placed two feeding vessels containing respectively sirup and nitric acid in suitable proportions. The liquor in the generator is then raised to about 180° or 200°, and the nitric acid and sirup allowed gradually to flow in by means of stop-cocks, so that the delivery of the whole may take eighteen hours, by which time the operation is at an end.

Meantime the gases given off from the decomposing sugar or sirup are carried off through a vent pipe issuing from the top of the generator into another vessel containing water. Here it meets with a stream of chlorine gas which decomposes the water, forming a mixture of nitric and hydrochloric acid vapors, which are received and condensed in suitable vessels.

In MACDOUGAL and RAWSON's patent process, the gases given off from the generating vessel are drawn by an air pump through a set of Woulfe's bottles containing water, into which air is also admitted. In this manner nearly the whole of the nitric oxide is said to be reconverted into nitric acid.

ECARNOT passes his gases mixed with a current of steam from a boiler, and with air supplied by a blast over surfaces of pumice-stone.

A variety of other processes for the manufacture of oxalic acid have been suggested, one of which, patented by Dr. WILTON TURNER, is certainly a curiosity, as it, like other absurd patent methods, involves the use of a material *much rarer and more expensive than oxalic acid itself*. He operates upon uric acid obtained from guano. This is to be boiled with water in which peroxide of lead or manganese is suspended. If lead is to be employed, a known weight of uric acid is put in an open iron cylinder sufficiently large to hold a quart of water for every pound of uric acid employed. Clear lime water is added, and the whole is made to boil briskly by a steam heat. Peroxide of lead is then added gradually, as long as it is

observed to be whitened by the liquid. About one hundred and sixty pounds of peroxide are required for every hundredweight of uric acid. The clear liquor is run off, the white sediment of oxalate of lead is washed and boiled with dilute hydrochloric acid. Chloride of lead remains as a precipitate, whilst oxalic acid crystallizes out of the solution. Another product of treating the uric acid with peroxide of lead is *allantoin*, which is converted into oxalic acid and ammonia by boiling with caustic potassa. The ammonia escapes, and may be condensed and collected in a suitable apparatus, whilst the oxalic acid is obtained as oxalate of potassa. The urea generated in this process appears to be wasted.

Uses.—Oxalic acid is employed principally as a discharging agent in certain styles of calico printing, for whitening leather, as for boot tops, and for removing ink and iron-mould from wood and linen. Its acid potassa salt, which serves for the same purpose, is sometimes most reprehensibly sold as *salt of lemons*, a practice which might easily occasion fatal accidents.

Oxalic acid, if taken internally to the extent of half an ounce or upwards, acts as a violent corrosive poison. The remedy is of course chalk, or any other form in which carbonate of lime is most accessible.

PAPER.—*Papier*, French and German; *Papyrus*, Latin.—Mankind have, in all ages and circumstances, except when sunk in the lowest state of barbarism, evinced a strong desire to transmit to posterity a record of their transactions, or something that would be a memorial of their existence and achievements. This principle is inherent in human nature, and has been implanted for the most beneficent ends. Without it the advantages to be derived from a knowledge of the experience and wisdom, as well as the crimes and follies, of preceding generations, would have been lost to posterity, and the history of the past could only have been gleaned from an obscure and uncertain tradition. To gratify this natural desire of living in future ages, men have resorted to various expedients. In the primitive ages they were satisfied with a stone, or a heap of stones, as a memorial of some important transaction; but when population became more dense, and more regular forms of government were established, huge structures were erected, which must have cost an almost inconceivable amount of labor and suffering, and of which the early architecture of Egypt affords the most remarkable example. Subsequently these structures were covered with hieroglyphics, and finally, the same object was more concisely accomplished by the art of writing, which was known at a very early period. The substances used for writing upon in primitive times were first stones and bricks, and afterwards leaves and the bark of trees. Besides these, lead, copper, wax, and wood, were also employed; in fact, almost everything that presented a smooth surface on which inscriptions could be made. Books are said to be in existence, the leaves of which are thin sheets of lead. Linen had also been used at a very early period, as is evidenced by the inscriptions upon the bandages of some of the most ancient Egyptian mummies. At a later date skins and the entrails of animals, and even bones, were applied to the same purpose.

PAPYRUS.—The material which eventually came

into general use, and nearly superseded all others, was the *Papyrus* of Egypt. It was made, as is generally known, from a reed or plant of the same name, which grew in marshy places, and along the banks of the river Nile. It is said to have grown in situations where the water was stagnant and only a few feet deep. At what time it came into use is uncertain. There is reason to believe, however, that its application as a writing material may be dated one thousand years before CHRIST. The prophet ISAIAH speaks of the paper reeds of Egypt as well known, and he lived nearly eight centuries before the Savior. The papyrus was undoubtedly the principal writing material which mankind possessed for many hundred years. As such it was highly valued and extensively used, and has transmitted its name to the material now universally employed. PLINY's account of the mode of preparing it is as follows:—The papyrus, says this writer, was cut before reaching maturity, being then in a soft and spongy state, and was divided by a peculiar needle into thin plates or pellicles, which were laid lengthways on a table alongside of each other, with their edges touching. Another layer was laid across at right angles. These were moistened with warm water and then pressed, which caused them to adhere, so that the two layers became one compact sheet.

It was believed that the water of the Nile possessed a gummy property, causing the layers to adhere in this manner. But BRUCE, the celebrated traveller, denies this, and affirms that while in Egypt he partly succeeded in making paper from the papyrus. He states that the plant contains a large quantity of saccharine matter, which warm water dissolves, and this being brought to the surface by pressure, acts as a glue or size. After it was pressed it was dried in the sun, and was then steeped in a size or starch, made by pouring boiling water on bread and filtering the liquor through a cloth, after which the leaves were again dried in the sun. The finer kinds used for writing are supposed to have been made from the inner part of the stem, while the coarser were made from the outer rind, and were used for packing.

There is some difference of opinion among writers in regard to this account; but the Editor conceives that the process may be explained by supposing, not that the reeds were cut into shreds or thin slices, but that, being composed of coats or layers, they were cut or slit up lengthways, and the successive laminae were easily stripped off one after another. Being in a soft and spongy state, they were fragile; and to render the process of stripping easier, the reeds were probably cut into lengths of ten or fifteen inches. The laminae being too weak singly to undergo the process of preparation were laid one over another and then pressed, which would greatly add to the strength of the article so prepared. When Rome attained universal empire, large quantities were carried thither; and there it underwent a higher degree of finishing, being steeped in a stronger size, dried, beaten with mallets, and smoothed with ivory. By these operations a high polish was given to its surface, rendering it probably equal in that respect to the modern enamelled, or at least glazed paper. The article so finished was cut

into a variety of sizes, but none exceeding two feet in length. Alexandria became the chief emporium of this manufacture. In that celebrated seat of learning it was carried on very extensively, gave employment to a great number of people, and was a most important branch of commerce. Towards the end of the Roman Republic the consumption of papyrus was very great, and it increased considerably during the reign of AUGUSTUS. The demand for it by other nations was also so considerable as sometimes to occasion a scarcity of it at Rome. A popular tumult which occurred there during the reign of TIBERIUS was said to have arisen from this cause. The manufacture probably reached its highest point of prosperity during the peaceful reigns of the ANTONINES; but the article continued for a long time in great demand, and the profit derived from it must have been very considerable. GIBBON, in his *Decline and Fall of the Roman Empire*, tells of one FIRMUS, a wealthy merchant of Egypt, who, taking advantage of the Emperor AURELIAN's war with Zenobia, raised the standard of revolt, assumed the Imperial purple, and, having obtained possession of Alexandria, boasted that he could maintain his army from the profits of the paper trade alone.

In evidence of the extensive use and admirable fitness of the papyrus as a writing medium, it may be mentioned, that eighteen hundred manuscripts of that material have been taken from the ruins of Herculaneum; that a manuscript in the British Museum, which appears to have been written about the year 572, measures eight and a half feet in length; and that one in Paris measures thirty feet. It appears to have been preserved in the form both of books and manuscripts. When bound in a book, a leaf of parchment was inserted between every five leaves; when kept as a manuscript it was in the form of a roll, which varied in length according to the number of sheets pasted together.

Under the Roman Empire paper or papyrus was loaded with a heavy tax, which seems to have been generally regarded as burdensome; for when THEODORIC, king of the Goths, abolished the tax, about the beginning of the seventh century, CASSIODORUS, a historian of that period, congratulates *the whole world on the removal of an impost on an article so essentially necessary to mankind*. It is somewhat remarkable that the British Government is the only one which, in modern times, has continued to follow the example of the Romans in levying this impost; and it is still more surprising that the ruler of a people whom it is the custom to associate with all that is rude and barbarous, should have set an example of enlightenment in dark and troublous times, which even the government of Great Britain, with all its boasted liberality, has not yet imitated. Fortunately, however, a resolution has at length been adopted in the imperial legislature, affirming the inexpediency of the tax on paper, and it cannot be doubted that the days of this barbarous and most impolitic impost are now numbered.

PARCHMENT.—Parchment is another substance which was much used in early times. It is made chiefly from the skins of sheep and goats, and is said to have been invented by EUMENES, a king of Pergamus, who reigned

about two hundred years before CHRIST. It is related that this monarch resolved to collect a library which would equal or excel the famous one of Alexandria; and this so offended PTOLEMY king of Egypt, that he prohibited the exportation of papyrus. EUMENES would not, however, be diverted from his purpose, and he, therefore, had recourse to the skins of animals, the manufacture of which he so much improved as to be termed the inventor of the material. Hence the word *parchment*, from *Pergamus*. At the same time, it is certain that the skins of animals, though less perfectly prepared, were used long before the time of EUMENES, and are spoken of as being employed among the Ionians more than four hundred years before the Christian era.

LEAVES.—The leaves of some kinds of plants, after undergoing a process of drying and rubbing, make a tolerable kind of writing material. Mr. HERRING says that the natives of India use them in preference to paper for ordinary correspondence, and even in important matters. This may arise from a strong attachment to old customs, and not from any alleged superiority in the material. So lately as fifty years ago a Persian manuscript was in existence, supposed to have been written on some kind of leaves.

The substances above enumerated were all used for writing upon; but, however suitable for that purpose, they were altogether useless for printing. The papyrus was too hard and brittle either to receive an impression, or to undergo heavy pressure. The mode of writing upon it, which was with a style or sharp metallic point, shows that it was not suitable to be printed upon. It is, therefore, by no means wonderful that printing was not discovered in the earlier ages of the world.

The relics of Assyrian art which have lately been brought to light, show that the Assyrians had really discovered the art of printing, as far as their materials would admit; and their progress in that direction seems to have been stopped, rather from want of suitable means than by any deficiency of ingenuity. The impression of the foot on sand might, to an observing mind, suggest the idea of printing, as that of weaving might be suggested by the web of the spider. But in the operations of nature, so far as they are open to ordinary observation, there is nothing analogous to papermaking; and indeed it is difficult to understand how any person could conceive the idea of reducing a vegetal to a liquid fibre, for the purpose of obtaining by deposit a thin smooth flexible sheet of considerable strength, and calculated to receive a permanent impression either by writing or printing.

PAPER.—The substances hitherto mentioned have all been natural productions. The labor required to fit them for their intended use, was preparation rather than manufacture, and did not affect their texture. With paper of modern manufacture the case is totally different; its only similarity to leaves and the papyrus consists in its being composed of vegetal matter. In commencing a short historical notice and description of this manufacture, it will be necessary first to define what really constitutes paper.

It is a universally admitted axiom that the meaning of any word is determined by the sense in which it has

long been used. According to this rule, the substance now called *paper* is an aqueous deposit of any vegetal fibre, radically different in its structure from all bodies formerly used for writing upon, being a highly artificial material, and having no resemblance in its texture to any natural substance. A sheet of paper should be of equal thickness throughout, so porous as to admit of an indelible impression, and yet so compact as to undergo without injury almost any pressure. The surface should be so smooth as to be easily written upon, and the sheet so flexible as to fold without cracking. It may be of any *color*, and of any *length*; but seven feet is the greatest *width* to which it has yet been extended.

HISTORICAL NOTICE.—Very little information can now be obtained of the invention and early progress of the art of papermaking. The earliest accounts do not agree either in regard to date or place; but all point to the East as the seat of the discovery, leaving almost no doubt that the principle of the modern art of reducing vegetal fibre to a liquid state is a Chinese invention, dating from about the beginning of the Christian era. A detailed notice of the mode of manufacture supposed to be practised by the Chinese, is given in the *Encyclopædia Britannica*; but, besides that the accuracy of this account may be doubted, the process involves an amount of labor which would render it impracticable in Europe. A great variety of materials appear to be used, all of them vegetal substances reduced to a liquid fibre. The paper produced resembles what is commonly termed *filmsy*, but takes a finer and more delicate impression from copper plates, and is known by the name of *india proofs*. A small quantity of it is used in this country for the finest engravings. It is generally made of the inner bark of the bamboo and cotton tree.

The first accounts of paper bearing any resemblance to the article now manufactured, date from the beginning of the tenth century. It is generally supposed, says the writer in the *Encyclopædia Britannica*, that the paper called *charta bombycenia*, which was invented in Greece, supplanted the Egyptian papyrus, and this paper is incomparably more lasting, and better calculated for all the purposes of writing. It is not precisely known at what period this art, which supposes a great variety of experiments, was first reduced to practice. Whether or not the Greek mode of making paper was imported from China it is now impossible to determine. Some accounts state, that paper was brought by the Arabs to Mecca in the eighth century, along with a knowledge of the art, and by the end of the ninth century they had carried it to the coasts of Barbary and Spain. GIBBON says, that the knowledge of the inestimable art of making paper from linen rags was diffused from the manufactures of Samarcand over the Western world; and in a foot-note he adds, that the librarian CASSIRE relates from credible testimony that paper was first invented, or rather introduced, at Mecca by JOSEPH AMRU, in the year 706 or 710. The Escorial library contains a manuscript on paper of this kind as early as the tenth century. There is little information of the progress of the art during the three following centuries, or even until the beginning of the fourteenth. From an American work,

The Chronology of Papermaking, it appears that in the year 1085 the Christian disciples of the Moors worked the paper-mills at Toledo in Spain to better advantage than their predecessors, and that instead of cotton they used rags, and made the paper with moulds. From the time, however, that paper was manufactured from fibre, moulds or sieves must have been used; and this probably refers, therefore, only to some important improvement which was effected upon them. It is stated in the same work that in the year 1151 the best paper was made at Xativa from rags. At this date also occurs the first notice of water-mills and the use of mallets. But from the disorganized state of society in Europe during this period, it could hardly be expected that an art like papermaking, which even in its simplest form requires an outlay of considerable capital, could make much progress.

The art reappears in Germany towards the end of the fourteenth century; but it is stated that even from the beginning of that century paper-mills were in operation in Tuscany. A mill was erected at Nuremberg in Germany to make paper from linen rags, by ULLMAN STROMER. At this time the process was kept strictly secret, and the workmen were sworn not to divulge it or carry it on on their own account. Notwithstanding all these precautions to keep the art secret, it became known, and was introduced into France, Holland, and Genoa, in all of which it seems to have been prosecuted with considerable success, particularly in France, whence there was a considerable quantity exported to Britain and other countries. The trade began to decline in France about the middle of last century, as other countries, particularly Britain, were by that time manufacturing nearly sufficient for their own use.

The first paper-mill in England, of which there is any particular account, was erected at Dartford in Kent in 1558, by Sir JOHN SPIELMAN, a German jeweller in the employment of Queen ELIZABETH, who, for services rendered in this respect, bestowed upon him the honor of knighthood, and gave him a license for the sole gathering of rags for ten years. Mr. HERRING says, it is quite certain that paper-mills were in existence long before SPIELMAN's time, and adduces a passage in SHAKESPEARE's play of *Henry the Sixth*, in which reference is made to a paper-mill at least a century before this; but he admits that the chronological accuracy of SHAKESPEARE is not to be depended on, and that the earliest traces of the manufacture in this country occur in a book published by CAXTON in 1490. The mill to which reference is supposed to be made, was near Stevenage in Hertfordshire. In the household book of HENRY the Seventh, there is an entry of a reward of sixteen shillings and eightpence given to the *paper mylne*, dated 25th May, 1498; and again in 1499 another reward of six shillings and eightpence is given to *Tate of the Mylne*, supposed to be the mill at Stevenage.

In Scotland the manufacture is of still more recent date. The first paper-mill, according to current accounts, was erected at Netherlee, near Glasgow, by a Dutch papermaker. The calamities which befell Scotland during the reigns of the last three STUARTS

prevented the introduction and development of manufactures; but after the Revolution, when protection was afforded to life and property, papermaking, like other manufactures, began to revive.

The French protestants who fled to England for refuge from the persecution which followed the revocation of the edict of Nantes in 1685, are said to have introduced many improvements into the paper manufacture. About this time white paper, of which little had been made, began to be more generally manufactured, and the quantity rapidly increased. It was estimated that about three hundred thousand reams were produced in 1721, and this was supposed to be about two-thirds of the consumption of the country.

MATERIALS FROM WHICH PAPER IS MADE.—The materials of which paper is manufactured are vegetal substances containing fibre, and are not so limited in number and kind as is commonly supposed. Linen and cotton rags, affording the greatest facilities of manufacture, have most generally been used, and are nearly all made into white paper. The rag merchant packs them according to their quality, and when brought to the mill they are cut, and assorted more perfectly. A large quantity of the rags used in this country are imported, and are principally of linen.

Ropes and the sweepings of cotton-mills, called *cotton waste*, furnish a large supply of material for papermaking. Incongruous as these may appear, they are generally used together, and when properly prepared make a beautiful paper, but require a great amount of labor. *Wrapping paper*, for which great strength is the most important requisite, is generally made from these materials; and they can be used for that purpose with comparatively little labor. But the American makers are in advance of the British in the use of these stuffs. By a peculiar process of cutting, cleaning, and boiling, Mr. H. V. BUTLER of New Jersey has succeeded in making from them the best printing papers which the Editor has yet seen. The sweepings of flax-mills, called *flax waste*, are very useful in making strong wrapping paper, where beauty of appearance is not an object, and furnish a considerable supply to the manufacturer. The best kinds can be used for white paper, but require much labor in preparation. Jute, surat, or nettle bagging, all of which appear to be substances of a similar kind, are now extensively used in making colored and brown papers. They are grown in India, and are made into bags, in which form they are imported into this country.

Straw.—Chemical science has also introduced straw—chiefly that of wheat—into the category of materials used for papermaking. When intended for printing papers, it requires to be boiled in a strong lie, to destroy the silica it contains. The fibre is short and tender, and not calculated to make of itself a good paper. It is, however, improved by being mixed with a stronger substance. Although it is only lately that straw has been successfully used for this purpose, yet as early as 1756 an attempt was made to manufacture paper from it in Germany, and in 1800 the Marquis of SALISBURY presented a book to the king printed on paper made from straw. In 1812 a Frenchman announced a new method, so simple that any person

could make paper from this material in a manner equal to the best workman, and in 1820 M. HUYGERON, another Frenchman, obtained a patent in France for a similar process. In 1828, WILLIAM MAGAW of Chambersburg, U.S., took out a patent for making paper from straw and blue grass. In 1854, M. KELIN of Belgium invented a process for converting straw into paper, which differed from any other in use. The straw was steeped in water sixty hours, when the liquid was run off and the straw washed with a plentiful supply of water. It was then passed between two rollers in a damp state, and afterwards cut into fibres of suitable length, and exposed to the bleaching effect of the sun's rays. It was now submitted to another bleaching process of three or four days, and subjected to the action of a solution of chloroxide of sodium or potassium, until it acquired a sufficient degree of whiteness, when it was put into the engine.

In 1857 another new mode of preparing straw was said to be discovered, but is not yet made public.

Wood.—The linden tree or bass wood affords another material for making paper, and several mills in the United States are at present employed in manufacturing it from this substance. The first attempt to apply it seems to have been made in France in 1776. Other kinds of timber have also been used; and in 1836 R. and J. C. MARTIN secured a patent for obtaining a pulp from wood, by first saturating with water planks or chips, then subjecting their surfaces to a cylinder having teeth resembling a saw or rasp, by which the ligneous fibre was reduced to a pulp. Sanguine hopes were at one time entertained that this plan would prove successful, but the Editor has not heard of its having been seriously adopted by any papermaker. It is difficult to reduce wood to a fibrous liquid, as the fibre is short and weak; and no means have yet been discovered of converting it into a pulp of the requisite fineness without, at the same time, reducing it to powder. If pine wood could be sufficiently bleached and pulverized, a portion of it might be used among pulp with advantage, as the resin it contains would improve the size.

Animal and other Substances.—Several attempts have also been made to fabricate paper, either wholly or in part, from animal substances, but hitherto with little success. Chamois leather, when properly prepared, and a portion of it mixed with pulp, makes a strong tough paper, but of a poor color. The machinery for preparing rags is unsuited for animal substances, its effect being to tear out, while animal materials require to be bruised or rubbed. Paper from such materials was lately manufactured at a mill in England, and was expected to be free of duty, but the case was otherwise decided.

From this enumeration it will be seen, that the field from which the papermaker can draw his raw material is not so confined as has been supposed; and these are but a portion of the substances which have been proposed and experimented upon. Mr. HERRING remarks that the fibre of vegetables which is capable of being made into paper may generally be first manufactured into some other fabric, such as cloth, ropes, or mats, and after it has served its purpose in that form it is then a

fit material for making paper. And in regard to experiments with new substances, he quotes Dr. FORBES ROYLE, who observes, that the generality of modern experimentalists seem totally unacquainted with the labors of their predecessors, many of them commencing improvements by repeating experiments which had been already made, and announcing results as new which had been long previously ascertained. As an evidence of the number of substances which have been tried, this writer refers to a book in the British Museum, printed in Low Dutch, and consisting of upwards of sixty specimens of paper, manufactured from as many different materials, all the result of one man's experiments, and made previous to the year 1772. In point of fact almost every vegetal has been tried. Nettles have always been a favorite article with experimentalists. It is not long since it was announced that hollyhock stalks were to furnish an almost inexhaustible supply for the papermaker. There is no doubt that it is possible to reduce every vegetal to a fibre, and with it to make paper. But notwithstanding all the discoveries of new substances which have been made, and all the protection which patents can afford, it is still found that flax and hemp, or rags, ropes, and other fabrics composed of these substances, constitute the staple materials of the paper manufacturer. And the Editor believes, that until science makes further discoveries in the mode of preparing new substances, papermakers will find it more profitable to abide by the use of the old materials, than rashly to indulge in experiments on their own account.

Supply of Materials.—Judging from the past history of papermaking, there does not seem to be much reason to fear that the present sources from which the paper manufacturer draws his raw material will ever be insufficient to supply the demands of the trade. The fact that it has always been when this manufacture was first introduced into a country that there was any considerable difficulty in obtaining the raw material, and that as the manufacture extended the supply also increased in about the same ratio, would seem to warrant the conclusion, that fears on this subject are groundless, so long as the present sources of supply exist. On the other hand, it must be taken into account that the countries from which the largest quantity of rags is imported are those along the shores of the Baltic and Italy; and were these countries to commence manufacturing for themselves, the supply from them would cease. At the same time, in proportion as civilization extends and population multiplies, new sources will open, and long before an absolute deficiency is felt, science may discover new materials as well as new processes.

The Editor has found some difficulty in reconciling the conflicting statements regarding the importation of rags into this country; but it appears that nearly a seventh part of the raw material is imported. In the year 1853 it was estimated that ninety thousand tons of rags were used in the paper manufactories of Great Britain, of which fifteen thousand tons were imported; but that, taking that year with the two preceding ones, the average annual importation was below ten thousand tons. In that year there was charged with duty, one

hundred and seventy-seven million, eight hundred and thirty-three thousand, and ten pounds of paper, besides about two hundred thousand pounds imported; and thirteen million, two hundred and ninety-six thousand, eight hundred and seventy-four pounds were exported, leaving for home consumption one hundred and sixty-four million, five hundred and thirty-six thousand, one hundred and thirty-six pounds. If, therefore, a seventh part be deducted from the total quantity charged with duty and imported, as representing that which had been made from imported rags, there remains only one hundred and fifty-two million, four hundred and twenty-five thousand, two hundred and ninety-two pounds; or there would have been a deficiency of upwards of eleven million pounds had this country been confined to the home market for its raw material. The discovery, therefore, of some new substance, which would really meet the wants of the paper manufacturer, and which could be provided at a cost not above the present price of rags, would undoubtedly be a national boon.

As these remarks may bring upon the papermaker a multitude of suggestions, and load him with specimens of all sorts of vegetals, from cabbage stalks to bamboo branches, the Editor would advise discoverers of new materials for making paper to work out their own suggestions, and first to ascertain the cost at which the proposed materials could be obtained, and also the cost at which they could be made fit substances for the paper manufacturer, before introducing their discoveries to public notice or incurring the expense of a patent.

PREPARATION OF RAGS.—The proper preparation of the rags is an object of great importance to the papermaker, and one which requires both skill and attention. It is, moreover, a subject on which opinions are divided. In these circumstances it will be sufficient to describe the mode of preparing the rags at the most extensive mill in this country, where the best writing and printing papers are manufactured.

Cutting the Rags.—The first process is the cutting of the rags, which is performed by females. Each woman is stationed at a small table about three feet square, and covered with a netting of wire. In the centre of the table a knife, about eighteen inches long and five inches wide, is placed nearly vertical. The woman stands at the back of the knife, and a quantity of rags are given to her, of which she lays a small portion on the table. She then cuts the rags into strips three or four inches wide, taking off buttons, hooks and eyes, *et cetera*, and laying out all substances unsuitable for the making of paper, such as india rubber, and pieces of woollen and silk. At her right hand is a box divided into several compartments, into which she throws the rags according to their qualities. A large quantity of sand falls through the meshes of the wire-cover into a box underneath. All pockets and seams should be ripped up to allow dirt to escape, and to prevent, as far as possible, anything getting among the prepared rags which would be injurious to the paper, or hard substances, such as pieces of iron, which might break the machinery.

The rags are again examined by women called *overhaulers*, or *overlookers*. There is generally one

overhauler to every eight or ten cutters. Some manufacturers attach great importance to having their rags cut into pieces four inches square. But the mere size of the rags is a matter of indifference. The principal object is to have them in a state which will insure their thorough cleansing in future processes, and cause them to float among water in the rag-engine without twisting and warping round the roller. Anything smaller than is necessary for this purpose causes a greater loss of fibre in the willow and duster.

Willowing of Rags.—From the overhaulers the rags are taken to the *willow*, which consists of two cast-iron cylinders, two and a half feet diameter, and three and a half feet wide, covered with iron teeth projecting about four inches. These cylinders are set one behind the other. Below them is placed a semicircular screen, and a cover of the same shape above. This cover is also provided with teeth, and is adjusted so that the teeth in the cylinders pass those in the cover at a distance of a half or three-quarters of an inch. In front are a pair of rollers and a revolving apron, for the purpose of carrying the rags into the cylinders. These revolve with a rapid motion, and the rags, being thrown by the first into the second, are confined in the cylinders about twenty seconds, when a sliding door, which rises three times in one minute, allows them to be discharged into a duster. As often as this sliding door opens, the revolving apron moves forward, and charges the willow with a fresh supply of rags. The latter, being thus beat and teased in the willow, are loosened in the texture, and a large quantity of sand falls through the screen underneath.

The *duster*, into which the rags are discharged after passing through the willow, is a large cylinder twelve feet in length and five or six feet in diameter, which is placed lengthwise against the willow, and revolves slowly at right angles to it. This cylinder is covered with a coarse wire-cloth, and a number of teeth are fixed into it at regular intervals, which toss and shake the rags, thereby removing any remaining dust, which falls through the meshes of the wire-cloth. The rags are now deemed ready for boiling. About five hundredweight of rags are carried through the willow in one hour. Cotton and flax waste is passed two or three times through the willow.

In willowing there is a considerable loss of fibre, particularly when the process is repeated more than once. The willow dust is therefore preserved, and is used in some inferior mills for making wrapping papers.

Boiling.—Rags are boiled in a solution of alkaline lie made of quicklime and soda, generally in the proportion of one pound of lime to two of soda. This caustic alkali is prepared by boiling the lime and soda together. While seething it should be well stirred and mixed, and afterwards allowed to stand for a few hours, until the sediment falls to the bottom, when a clear liquid is obtained. The quicklime is first thrown among the hot water, and some think it improves the lie to introduce the soda immediately, while the lime is slaking, as a high degree of heat is then evolved, which dissolves the soda very quickly. Others slake the lime in a cistern by itself, and after stirring well, allow the heavier and undissolved portion to fall to the

bottom, then run off the upper portion, which has the appearance of a fine thick cream, into another vessel, and afterwards put in the soda. Another method is to dissolve the lime as above, and run it into the boiler among the rags; the quantity of soda to be used is then put into a bag, which is introduced into the boiler and its contents allowed to dissolve. But the general way is to mix the lime and soda, and run the pure liquid into the boiler. For the finest papers this liquid should be quite pure. Six to ten pounds of soda, and three to five of lime, are generally used for one hundred-weight of rags; but this proportion varies according to the quality of the rags, and every manufacturer has his own method of procedure.

Rags are boiled for the purpose of *killing*, or destroying, minute particles of the stem of the flax and shell of the cotton, which even very fine cloth contains. These substances, which are generally called *shove*, are very injurious to paper, and boiling is the only way to get rid of them. It also loosens the dirt in the texture of the rags, and considerably improves their color. A strong flax rag will lose from one-third to one-fifth of its weight by boiling and washing.

It is not more than thirty years since papermakers began to boil their rags, and the boiler long used was simply a cast-iron vessel, large enough to contain about ten hundredweight of rags. It had a furnace underneath, and was heated by the direct action of the fire. The chief objection to this mode was, that pieces of rags adhered to the sides of the boiler, and were burned. Steam was then tried, and found to be much cleaner in its operation. Circular, and sometimes square boilers, were adopted. When steam came into use, a perpendicular pipe was inserted into the centre of the boiler, which had a double bottom, the upper one being of movable perforated plates, and raised about nine inches above the lower. The steam was admitted from the top, and passed by the vertical pipe into the space between the bottoms, where it escaped into the boiler by tubes radiating from the central pipe to the sides of the vessel. This is still considered by many manufacturers to be a good boiler. An addition was made to it by some papermakers, who inclosed the steam pipe in a larger one, leaving a space of two or three inches between the two. When the liquid containing the rags was brought to the boiling-point, it was forced up between these pipes; and round the top of the outer one was a large flange, which spread the lie over the surface of the rags. A constant circulation was thus maintained by the rising of the lie in the space between the pipes, and its subsequent descent through the rags contained in the body of the vessel. This is reckoned a good boiler, and is still used by a number of papermakers. It is generally made seven feet in diameter by four deep, from the rim to the false bottom, and will boil ten or twelve hundredweight of rags in twelve or fifteen hours. It is known, from its peculiar action, as the *vomiting boiler*.

The apparatus now in greatest repute is the *revolving boiler*, of which at least three different kinds are made. This form of boiler was first applied by H. V. BUTLER of New Jersey twelve years ago. It is a large iron cylinder revolving horizontally on bearings, and divided

into four compartments with double ends; the inner ends being perforated plates by which the boiler is drained, and provided with a small door, large enough to admit a man, by which the vessel is filled and emptied. This boiler operates with less soda, and the boiling is performed in from eight to ten hours. Revolving boilers were first introduced into England about the year 1854 by BRYAN, DONKIN, and Company, of London, who secured a patent for a boiler on this plan. It consists of two iron cylinders lying horizontally, one within the other. The outer cylinder is stationary, while the inner, which is perforated, is so constructed as to

revolve. There is a frame and rack in front, by which the inner cylinder can be drawn out; two large plates are then taken off and the cylinder turned round, when the rags fall out. The front end is bolted on to the outer case, and keeps the boiler steam-tight. In this apparatus the rags require only from eight to ten hours' boiling, and a small saving of soda is effected.

Another revolving boiler has been patented by Mr. JOHN ROBERTSON, engineer to Messrs. A. COWAN and SONS, Valleyfield, near Edinburgh. This apparatus is represented in Figs. 379 and 380. It consists of two cylinders; the outer one, A, is made of boiler-plate,

Fig. 379.

Fig. 380.

and is rivetted to cast-iron flanges, B, which revolve slowly on four friction wheels, C, fixed on two shafts, D, with spur wheels, E, on one end of them for receiving a motion. The inside cylinder is formed of perforated iron plates, with bars or shelves, F F, projecting inwards, for the purpose of agitating the rags. The steam and lie are admitted through the centre of the back end, H, of the boiler, in pipes, G G, leading to the space between the two cylinders. The rags are put in and taken out by removing the other end, K, of the boiler, which end or door is also made of boiler-plate, and is rivetted to a cast-iron flange with a turned face, fitting into a corresponding groove in the flange on the body of the boiler, and secured by strong bolts, making a steam-tight joint. This boiler is calculated to stand a pressure of sixty pounds per square inch, thereby subjecting the rags to a higher temperature than that of boiling water.

An opinion prevails that a high degree of heat is beneficial in boiling rags—that by using high-pressure steam a smaller quantity of soda is required—while by having the boilers steam-tight this high pressure is kept up with a small expenditure of steam. In practice it has been found that, while boilers constructed on this principle effect a considerable economy of time, there is no great saving of alkali, and that a small escape of steam is positively beneficial.

A different system of boiling has been patented by Messrs. CRANSTON and LOVELL of Chirnside. Their apparatus consists of a series of oval stationary boilers,

each containing about seven hundredweight of rags. These are likewise heated with high-pressure steam, which passes from one to another; and the boilers being steam-tight, only a small quantity of steam is required, while a saving of alkali is also effected. The Editor believes this mode of boiling has given satisfaction to those who have adopted it. Strong and perfect boiling is a highly important point in papermaking, and contributes greatly to the production of a clean and pure article. Any defect in this operation can never be remedied by subsequent processes.

Washing Engine.—The rags, after being boiled, are brought to the *washing engine*, which performs a very important part in the manufacture of paper. This engine, which is represented in Fig. 381, is a large iron vessel, into which the rags are put for the purpose of cleansing and reducing them to what is called *half-stuff*. For this purpose the rags are made to revolve among water, a constant supply of which flows in at one end of the vessel, and an equal quantity is lifted out at the other by means of a revolving cylinder covered with wire cloth. This engine is of various sizes, generally about twelve feet long, from four to five feet in width, and two deep. An iron partition runs about eight feet along the centre, leaving a space of two feet open at each end. A few perforated plates are placed in the bottom to allow any sand or dirt to escape, and a grooved box in front of the roller to catch any buttons or hooks, or other hard substances, which may have escaped former processes. Across the centre of the

engine is a spindle, A, of wrought-iron, four or four and a half inches diameter, one end of which carries a pinion, B; the other end rests on a frame or lighter, C C, which can be raised or depressed by means of a screw, D. On this spindle is an iron cylinder or roll, E,

Fig. 381.

generally twenty-four inches in diameter by twenty-eight inches in length, and mounted with forty bars or knives at regular intervals, projecting about two inches, so as to make the extreme diameter twenty-eight inches. The roll makes from one hundred and twenty to one hundred and thirty revolutions per minute, and under it is fixed a plate composed of ten or twelve knives, five or six inches wide, and equal in length to the roll. This plate is fixed in a box or seat, F, in the bottom of the engine. Over the roll is a wooden cover, to prevent the rags and water from flying off by the rapid revolution of the roll; and across this cover is placed a screen of fine wire-cloth, against which the rags and water are dashed by the motion of the roll. In the figure, the cover and screen are removed, to exhibit the internal apparatus. The water, passing through the screen, is carried off by pipes, while the wire-cloth prevents the rags from escaping. Formerly these screens, one before and one behind the roll, were the only means of carrying off the dirty water.

In the year 1837, CHARLES COWAN of Valleyfield Mills invented and patented a revolving washing cylinder, which greatly improved the washing power. This cylinder, which consists of fine wire-cloth, contains a series of circular buckets, starting from a common centre on a spindle, and projecting to the circumference of the cylinder. The latter is twenty-four inches wide by thirty inches diameter, and being immersed in the engine to the depth of six inches, revolves among the rags, while the buckets successively lift the water and pour it out at the centre into a spout. When the engine is empty the rags are brought to it in a box. The roll is lifted entirely free of the plate by means of the lighter screw. A stream of water is then turned into the engine; and as soon as it rises to the level of the roll the workman begins to introduce the rags, spreading them on the surface of the water. About a hundred and fifty pounds are put in at one time. The rotatory motion of the roll draws the rags between the roll and plate, and dashes them from one side to the other, until, being carried round in the spaces between the knives, they are thrown out on the other side. By this action the level of the water is depressed in front of the roll, and on passing through to the other side, it endeavors to regain its level, whereby it flows round the end of the mid-

feather, back to the front of the roll. A continuous circulation of the rags is thus maintained, and the flow of water into the engine is regulated by the quantity lifted out, which is greatest at the commencement; for as the rags are rubbed down into fibre less water is lifted by the washing cylinder. Papermakers calculate on the washing engine using from forty to sixty gallons of water per minute. When the rags have been fifteen to twenty minutes in the engine the roll is gradually lowered, until nearly its whole weight rests on the plate.

The motion of the roll over the plate draws the rags into a fibrous substance called, as already stated, *half-stuff*. Experience and care are required in this operation. If it is performed too quickly, or if the rags are cut too short, the paper will be weak, and a great loss of fibre in future operations will be the consequence. If, on the other hand, the rags are not drawn into fibre they do not bleach equally. It requires not less than two hours to reduce the rags to half-stuff; by this time they should be cleansed, and in a fit condition for being bleached.

In the process of washing the rags a considerable quantity of fibre passes away with the water. To save this fibre, which can be used for inferior papers, Messrs. JAMES PAISLEY and GEORGE BERTRAM have invented and patented a conical cylinder covered with fine wire-cloth. The water, as it passes from the engine, enters the small end of the cylinder, and as it flows down to the wide end, percolates the wire-cloth, leaving whatever fibre it contained. This cylinder can also be applied to recover the fibre which the waste water from the machine contains.

Several other improvements have been made at different times upon the washing engine, professing to increase its washing power and save fibre; but none of them, so far as the Editor is aware, have proved of practical value.

Bleaching.—The quality which chiefly distinguishes the paper of the present day from that made thirty or forty years ago, is its pure white color, which can only be obtained by bleaching. When the art of decoloring with chlorine gas was introduced about the end of last century, manganese and chloride of sodium were mixed together in a close vessel, and sulphuric acid was poured upon them. The chlorine thus generated was conveyed in pipes to a close chamber, in which were placed the rags to be bleached. In the chamber they were exposed to the action of the gas for some hours, and by this means a good result was obtained; but it was a difficult operation, and injurious to the health of the workmen.

When chloroxide of calcium, or lime impregnated with chlorine, was introduced, the method first practised was to put the lime into an iron or lead box and mix it with water. The gas, having a stronger affinity for the water, combined with it, forming what is called bleaching liquor. When the rags had been well cleansed in the washing engine, and reduced to a coarse fibre, as already described, the flow of water through the engine was stopped, and a portion of the bleaching liquor was introduced among the *half-stuff*. The roller was then lifted off the plate, and the stuff was made to circulate in the engine about an hour, which effected a great

improvement in the color. The process of washing was then resumed, and continued until the gas was washed out, after which the stuff or pulp was emptied into the beating engine.

To this method there were several objections, one of which was that the whole of the gas that remained in the stuff when the washing was resumed was lost. About 1820 the present method of bleaching in stationary chests, and thereby saving the liquid which still retained a considerable quantity of gas, was generally adopted by manufacturers.

Present Method of Bleaching.—A quantity of chloroxide of calcium is put into a circular stone cistern filled with water. An upright shaft, which revolves on a bearing in the bottom of the cistern, and has arms projecting to within a few inches of the side, mixes the bleaching powder with the water. When the agitator is stopped, the lime settles to the bottom, leaving a clear liquid with a green tinge, which constitutes the *bleaching liquor*. The proportion of lime and water is generally one pound of lime to two gallons of water, and it is expected to stand 8° of Twaddell's hydrometer, but seldom stands more than 7°.

When the rags have been brought by the washing engine to a fit condition for being whitened, they are emptied into the bleaching engine, which is placed on a lower level to admit of the stuff being discharged into it by a pipe. The bleaching engine is similar in construction to the washing apparatus, but has no plate, as its only office is to mix the stuff with the bleaching liquor. It is made of stone to resist the action of the chlorine, and a part of the bottom is laid with perforated zinc plates, to admit of the stuff being drained. This is generally done by a pump, and the water is used over again for washing the next charge of stuff. When this half-spent lie has been introduced into the bleaching engine, there is added to it a portion of strong liquor, generally from eight to sixteen gallons to the hundredweight of rags. This quantity of bleaching solution contains as much gas as exists in four to eight pounds of lime. The stuff is then allowed to run from fifteen to twenty minutes, and is finally emptied into the bleaching-house, where it remains from eighteen to twenty-four hours.

The bleaching-house is a separate apartment, in which are generally placed two rows of stone boxes or chests, each of sufficient capacity to receive the contents of two engines of stuff. To allow sufficient time for bleaching, there ought to be as many chests or boxes as will contain the supply of stuff required for thirty hours.

Some papermakers allow the *half-stuff* and chlorine to remain from forty-five to fifty minutes in the bleaching-engine, under the impression that the color is thereby improved. It cannot be denied that the color improves very rapidly under the process; but when it is continued more than twenty minutes, the action of the roll on the stuff causes the chlorine to evaporate, which is easily perceived by the smell, and greatly reduces the bleaching powers of the liquor.

About four years ago Mr. DUNCAN of Denny invented a different method of bleaching, which he protected by a patent. The principle of his improvement

consists in the application of heat to the pulp while in the bleaching engine. According to his published statement, its advantages over the old method are, that it is more economical, produces a better pulp, and is more quickly effected; the whole process not occupying an hour. But whatever be its merits, it does not appear that this mode has found much favor with paper manufacturers.

When the stuff is sufficiently bleached, the clear liquid is pumped into a cistern for further use—it being a property of the liquid that it not only extracts but destroys the color, and, therefore, does not become impure by bleaching. On the other hand, the stuff or pulp is put into a strong iron box, and submitted to the action of a hydraulic press, which prepares it for the beating engine.

BEATING ENGINE.—The *beating engine* is of nearly the same construction as the washer, and is used for grinding the *half-stuff* into a fine pulp fit to be made into paper. The roller contains fifty-four, and the plate from seventeen to twenty-four knives. A stream of water is turned into the engine; the *half-stuff* is then introduced, and mixing with the water, is drawn between the roll and plate, producing a continuous circulation, as in the washing engine. Before the roll is lowered to the plate, the *half-stuff* is allowed to run for thirty or forty-five minutes, to wash out the chlorine, which, if suffered to remain, is found to be injurious to the paper.

Within the last few years hyposulphite of soda has been used to neutralize the chlorine. A small quantity of this salt is dissolved in water; and this, being put into the engine, instantly seizes the chlorine, and by combination neutralizes it, forming sulphate of soda, a substance harmless to paper. The washing is then resumed, and continued for a few minutes, to remove the new compounds formed. It may here be remarked that since hyposulphite of soda, or, as it is technically termed, *antichlor*, came into use, the time of washing in the beating engine has been reduced to twenty minutes, thereby effecting a saving of twenty-five minutes, which can be applied to the grinding of the pulp, and, at the same time, no traces of chlorine remain in the paper.

If the pulp is required for printing papers, a solution of soda and rosin is now put into the engine; and, after being well mixed, a few pounds of alum are added, which, combining with the soda, allows the rosin to adhere to the pulp; this is called *engine-sizing*, and is done with the view of preparing the paper to bear ink when printed. Any coloring matter which may be required is next introduced; the roll is then gradually lowered on to the plate, and the process of *grinding*, or reducing to fine fibre or pulp, commences.

The pulp is made long or short according to the quality of the paper. Newspapers, which require strength, are made of long pulp. Writing paper, or paper of a fine texture, is made of shorter pulp. In fact, the quality of the paper depends very much on the manner in which the pulp is prepared in this engine. If the roll is lowered too rapidly the fibre is cut, and produces a tender paper; and, owing to the porous nature of this paper, the sizing, whether for printing

or writing, will be weak. The stuff should be what is called *mellowed* in the engine, and this is effected by a judicious working of the roller—not lowering it suddenly or much at one time, on to the plate; but equally and gradually, until the pulp is ground as fine as is required. This is generally attained in three and a half to four hours; after which the engine is emptied into the stuff chest or reservoir, which is a large cistern capable of containing five thousand or seven thousand gallons of this prepared pulp.

To give an idea of the number of cuts or bruises to which the rags are subjected, it may be stated that the roll containing fifty-four knives revolves a hundred and fifty times per minute over the plate containing twenty knives, thereby making no less than a hundred and sixty-two thousand cuts every minute. This rotary engine was invented by the Dutch about the middle of the last century, and is known by German papermakers as the *Hollander*. Although not free from some defects, it is a great improvement on the old mortar engine. And while great advances have been made in papermaking during the last thirty years, the chief improvement on this engine has been the revolving washing cylinder, already described. The principal defect of the engine arises from this, that while a certain quantity of rags is put into it for the purpose of being ground to fibre or pulp, these rags are not of the same tenacity, and being kept under the action of the grinding process for three or four hours, the weaker rags are reduced to a finer pulp than those of a stronger texture. Also, one engine may be emptied into the reservoir which contains pulp of a longer or shorter fibre than the previous one. In fact, there is no security against this evil but the care and skill of the workman; and, notwithstanding every precaution, it sometimes materially affects the quality of the paper.

To overcome this difficulty, JOSEPH KINGSLAND of New Jersey has secured a patent for a centrifugal pulp engine, which is said to be working satisfactorily in his mill in New Jersey, producing a uniform pulp. This machine has been adopted by EASTON and AMOS of London, by whom further improvements have been made upon it, and who, having also experimented with it at Phoenix paper-mill, Dartford, state, that having now fairly tried it, they are convinced it is a valuable machine, one capable of producing better pulp with less power than any other engine hitherto produced; and that, consequently, its adoption would secure to papermakers very considerable advantages. Hence they are persuaded that it must come into extensive use.

This invention consists in placing a revolving grinder between two stationary grinders; the fibre to be ground or reduced to pulp being caused to pass in a current through the spaces between one of the stationary grinders and one side of the revolving grinder, thence round the periphery of the revolving grinder and the other stationary grinder, to the orifice of discharge. In its actual operation a stream of pulp well mixed with water flows by a feed pipe under, say, four feet pressure into the engine, between the revolving grinding surface, which makes two hundred revolutions per minute against the stationary grinder, and the distance

between the two surfaces can be regulated by a set of screws, thereby producing coarser or finer fibre as required. The moment the fibre is ground it passes into the reservoir. A constant stream is thus flowing through the engine at the rate of a hundred and fifty pounds of paper per hour. The Editor has no doubt but that in a few years this engine will supersede the present beating engine, and will greatly simplify the mechanical operations of the papermaker.

The thorough neutralization of the chlorine is an important matter. When machines began to be generally introduced, the engines in many mills were not adapted for the increased quantity of work a machine could perform, as compared with vats. Too little time was therefore given to the preparation of the pulp, and the chlorine was not sufficiently washed out; and as chlorine, if left in pulp, continues to act on the paper, causing a premature decay, complaints were consequently very frequent, and the decay was ascribed to excessive bleaching and the use of mineral substances. This, although a natural opinion, was not the less a mistake. Excessive bleaching will make paper weak or tender, but if the chlorine has been neutralized it will not otherwise injure it. Mineral substances were at one time pretty freely used, and in some mills this may still be the case. A small quantity is not injurious to paper, and is sometimes used to close the pores, thereby improving the surface. But experience has taught paper manufacturers that the injury these substances do to felts and wires is poorly compensated by any little addition to weight which is obtained from them; and since antichlor came into use, by which the chlorine is easily neutralized, the complaints above-mentioned have been seldom heard.

PAPERMAKING BY HAND.—Having described the method of preparing rags to make paper, the Editor will briefly advert to the old way of manufacturing it.

In papermaking, as first conducted in Europe, the rags were neither boiled nor bleached, but were only cut and assorted; and to facilitate the cleaning and reducing to pulp, they were steeped in water, then laid in heaps, and allowed to ferment and putrefy. This loosened the texture, and prepared them for being cleansed and reduced to pulp. The process of reducing the rags to pulp was performed by stamps or mallets working in a strong wooden box or mortar. A stream of pure water was allowed to flow through the box, thereby carrying off all impurities. This process was continued until the rags were clean, and was necessarily very slow and tedious. When the rags were considered fit to make paper, they were emptied into a chest, from which the pulp was lifted into a vat. This vat was simply a cistern about three and a half feet high, six feet square at top, and tapering nearly to a point at bottom; near which a small agitator revolved, keeping the pulp of an equal consistency throughout.

The sheet of paper was made by a mould, composed of a frame covered with fine wire-cloth, having a movable edge called a *deckel*. This mould the workman dipped into the vat, lifting a portion of the pulp on its surface. The water flowed through the wire-cloth, and left the fibre on the top. The workman then removed the deckel, and passed the mould to another,

who turned it over, and pressed it on a felt, to which the sheet adhered; the mould was then returned to form a new sheet.

About one hundred and thirty sheets were now laid in alternate layers of felts and sheets, and the whole submitted to powerful pressure, which forced out a large quantity of water, and made the paper sufficiently firm to bear handling. The sheets were then taken out of the felts, and being laid together, were subjected to another pressure, after which they were parted or turned over, to prevent their adhering to each other. The paper was then taken to a drying-house, and hung up on lines to dry; from four to eight sheets were hung together. In favorable weather the paper would dry in from three to five days, and in damp weather the drying-house was heated by steam. After being thus exsiccated, it was dipped into size or glue, for the purpose of closing the pores, and enabling it to bear writing upon. When sized, it was gently pressed, and each sheet parted from another, and hung up a second time to dry in the loft or drying-house.

The system of making paper by hand was very slow; it occupied at least three weeks from the preparation of the rags to the finishing of the paper, and often subjected the manufacturers to considerable loss. To work one vat, which would make on an average one hundred and fifty pounds of paper per day, or what can now be made by a machine in one hour, required eight men, and eight or ten women.

There are still a few vats working in the country, generally in the manufacture of paper for which great strength is required; and at Maidstone, in Kent, there are still two mills or factories engaged in hand-making. These were established about one hundred years ago by Mr. JAMES WHATMAN, and great improvements were introduced in them. The paper of one of these mills is still marked—J. WHATMAN, Turkey mill; that of the other is marked simply, —J. WHATMAN. The manufacture of these mills has not yet been equalled, whether by hand or machine made paper.

HISTORY OF THE PAPER MACHINE.—The paper machine, by which so great a development of the paper trade was effected, had its origin in France. LOUIS ROBERT, a clerk in the employment of DIDOT, was the first who appears to have conceived the idea of making a continuous web of paper on an endless wire-cloth, to which a rotary motion was communicated, thereby producing a web or sheet of indefinite length.

However simple this idea may appear to those who are acquainted with the present system of papermaking, it was nevertheless a most extraordinary conception at the time, and marks out the inventor as one of those original thinkers whose ideas, being worked out by men acquainted with details, have done so much to extend manufactures and benefit mankind.

About the year 1798, ROBERT constructed a small model of a machine, by which he could make a narrow continuous strip of paper. M. DIDOT, his employer, became interested in his labors, and with this gentleman's assistance, a machine was constructed by which paper twenty-four inches wide could be produced. But though this rude apparatus might be sufficient to

demonstrate the possibility of applying the rotary motion to papermaking, yet either from the impatience of its inventors, or more probably from its defective construction, it does not appear to have been used for practical purposes, but merely as a subject of experiment. At the same time its merits did not pass unnoticed. Although not immediately put into practical use in France, yet the French government, with just discrimination, presented to ROBERT the sum of eight thousand francs, as a reward for his invention, and the right to it was purchased by M. DIDOT for the sum of twenty-five thousand francs, while that gentleman's brother-in-law, M. GAMBLE, secured a patent for it in England, and also obtained an introduction to the Messrs. FOURDRINIER, who at that time were extensive stationers and papermakers. Messrs. FOURDRINIER entered with great zeal into the project, and under the superintendence of BRYAN DONKIN, they in three years succeeded in constructing a machine which made a continuous web of paper; but, after three years more of intense labor, and an expenditure of sixty thousand pounds sterling, the patentees found that their machine still required extensive alterations and improvements. They therefore applied to Parliament for an extension of their patent for fourteen years.

The bill passed through the House of Commons, but as stated by the late Dr. URE, by an unworthy artifice of Lord LAUDERDALE's, it was limited to seven years, with an understanding that the patent would be extended other seven years if at the end of the first period they could show that they had not been remunerated for their outlay. However, they were prevented from reaping the benefit of this arrangement by a standing order of the House of Lords, subsequently placed on their journal, which allowed an extension of a patent only to the original inventors. Messrs. FOURDRINIER being thus prevented from reaping any advantage, or deriving any remuneration in return for the capital expended, became involved in difficulties, which led to their bankruptcy.

To show the advantage of this invention, Mr. FOURDRINIER in 1806 published a statement, showing the cost of working a machine capable of doing seven vats' work, compared with the cost of working seven vats. He shows the cost of the latter to be two thousand six hundred and four pounds sterling per annum, which would now be considerably increased by the higher wages paid to workmen; the cost of the machine doing equivalent work he calculated at seven hundred and thirty-four pounds sterling per annum, and this, on the contrary, would now be diminished, owing to the improvements which have been made, and the greater quantity of paper produced in the same time. But taking his own figures, he thus demonstrated a saving, by his invention, of one thousand eight hundred and seventy pounds sterling upon seven vats in one year. The cost of making paper by vat he showed to be sixteen shillings per hundredweight; by machine only three shillings and ninepence; and in 1807 he offered to make such machines at from seven hundred and fifteen to one thousand and forty pounds sterling, according to their width. He also points out as another advantage of the machine, that of relieving the

manufacturer of all difficulties arising from combinations among workmen.

It is a lamentable fact, remarks the late Dr. URE, that the attention required to mature this valuable invention, and the large capital which it absorbed, led ultimately to the bankruptcy and ruin of this opulent and public-spirited company; after which disaster no patent dues were collected, though twelve suits in Chancery were instituted; these being mostly unsuccessful on account of some technical objections made to their well-specified patent by that unscientific judge, Lord TENTERDEN. The piratical tricks practised by many considerable papermakers against the patentees, are humiliating to human nature in a civilized and *soi disant* Christian community. Many of them have owned, since the bankruptcy of the firm removed all fear of prosecution, that they owed the company from two thousand to three thousand pounds each for patent dues!

PRESENT PAPER MACHINE.—When the pulp is properly prepared, it is emptied into the stuff-chest—in which an agitator revolves for the purpose of keeping the pulp and water at an equal consistency—and is thence drawn as required to suit the machine. Before describing the latter apparatus, it may be necessary to state that an important desideratum in paper is *uniform thickness*, and this can only be obtained by a uniform supply of pulp and a regular speed of machine. Formerly, this uniformity depended entirely on the care and attention of the workman; but in drawing the pulp to supply the machine by a pipe from the chest, the pressure was always varying and making irregular paper, and the workman could scarcely regulate his valve or supply-cock to the exactness required. When an engine of pulp was emptied into the chest or reservoir, the pressure on the valve was increased, and the workman, by his own judgment, had to lessen the orifice of discharge; but, however attentive he might be, he could not regulate the valve with perfect certainty, or in precisely the same ratio as the increase or decrease of pressure in the chest.

To overcome this irregularity in thickness, papermakers tried various methods, but the two modes in general use are by a pump and a pulp meter.

Pumps and Pulp Meters.—When pulp is delivered to a machine by a pump, the latter is applied to pump the pulp from the large chest into a small one placed above it, in which is an overflow, so that if the supply to the machine be rapidly stopped, the pulp will immediately flow back into the large chest. A regular quantity of pulp is thus kept in the small one, to which the supply-pipe is attached, and a uniform pressure is in this way obtained.

The other mode by *pulp meter* was introduced by Messrs. COWAN from OECHELHAEUSER, the foreign inventor, and consists in making the pulp, which is kept at an equal density, flow into a cistern, in which a box constantly dips, lifting an exact quantity of pulp. The capacity of this box can be increased or diminished, to correspond to the different thicknesses of paper required. The writer has seen this pulp meter work for twelve hours, and the workman in attendance never require to touch it, while the paper produced would not vary in weight one half pound per ream.

Lifter Wheel and Sand Trap.—From the pump or pulp meter the pulp flows into the *lifter wheel*, and is further diluted with water. This is a wheel composed of buckets, into which the *save-all* water flows, and is by them lifted to its former level for the purpose of being used again. The pulp and water are both lifted and discharged on to a *sand trap*, which is a long flat box from twenty to forty feet in length, and only four or five inches deep. The pulp flows over this surface, and allows sand to settle on the bottom. From this the pulp flows into the strainer.

The Strainer is a brass frame, of which the bottom is composed of brass plates finely perforated, and through which the pulp has to pass longitudinally, thereby keeping back all knots and impurities. A quick, vertical motion is given to it; the pulp flows in on the top, and percolates through the bottom by suction; it then passes into the vat. A great variety of these strainers are in use; but the best which the writer knows of is made by EASTON and AMOS of London. Their strainer is a fixture, and below it is a piston, which is made to work vertically against the bottom of the strainer, without touching it. A rapid motion is given to this piston, and the suction thereby created carries the pulp through. This patent strainer is a great improvement on the old one. While the latter has to be cleaned every twelve or twenty-four hours, this will work for sixty or seventy hours without cleaning.

The Wire.—From the strainer the pulp flows by two pipes into the vat, which is a large box for containing a supply of pulp, and from this it passes to the *wire*. The latter, which constitutes a most important part of the mechanism, is generally an endless web of fine wire-cloth, of three thousand six hundred to five thousand meshes in each square inch. It is about thirty feet in length, and is made to revolve on two rollers—always presenting a level surface of twelve or fifteen feet to receive the pulp. To admit this liquid to the wire, a slit or opening runs along the front of the vat, by which the depth of pulp is regulated. The latter flows through this opening upon an apron or delivery board, and from thence to the wire, beneath which is placed a box called a *save-all*. The lateral motion of the wire shakes the fibre of the pulp together, while the water passes through the meshes of the wire-cloth into the *save-all*, and thence into the lifter wheel, to be used over again.

The fibre being left on the surface of the wire, gradually becomes firmer and more compact; and is regulated in width by *deckel* straps or bands, which form ledges at or near the sides of the web, and prevent its flowing off the wire. These bands or deckels are made of a number of layers of cotton, gummed and sewed together, being about one inch in width, and half an inch thick; sometimes they are made entirely of vulcanized india rubber. They travel along with the wire, one on each side, and by their flexibility keep the pulp to any required width. They are guided by a frame which stretches across the machine, resting on its framework; and the breadth of pulp is regulated by widening or narrowing the frame.

The Dandy Roll.—Travelling with the wire, the

pulp passes to the dandy roll, which is simply a cylinder, the two ends of which consist of brass hoops fixed on a shaft, and having wires extended between them; or it is sometimes formed of perforated copper, and is covered with fine wire-cloth. It is generally seven inches in diameter, and usually corresponds in length to the width of the wire upon which it rests. The journals of this roll turn in slits in two upright stands; one behind the machine frame and the other in front of it; but, as the roll actually rests with its whole weight on the wire, it revolves by the progressive motion of the latter, while the stands prevent it from participating in the lateral motion. This roll, by running on the surface of the pulp, presses out a great quantity of water, and renders the paper finer and closer in texture.

The dandy roll appears to have been invented by Mr. JOHN WILKS, an English mechanist, for the purpose of pressing out some of the superfluous water. This object was afterwards more effectually accomplished by the pump-box, but the dandy was still found to be a valuable invention for closing the pores of the paper. It is also by this part of the mechanism that the water-mark and the lined appearance which laid paper presents are impressed.

Suction Boxes.—Beneath the dandy roll, and across the machine, two suction or pump boxes are placed, having their upper sides open. As the wire travels over these boxes, the action of the pumps with which they are connected draws the wire upon them with a pressure sufficient to make them air-tight, thereby extracting a large portion of the water which the pulp at this point still retains, and giving to it such a degree of consistency as fits it to bear without injury the pressure of the couch rolls. Before this apparatus was introduced, the pulp often came too wet to the couch rolls, causing the paper to be water-galled.

The Couch Rolls.—The web of paper being regulated in width by the deckels, rendered closer in texture by passing under the dandy roll, and made drier and more compact by passing over the suction boxes, now arrives at the couch rolls. These are two large rollers covered with felt; the under one revolves inside the wire, and gives the motion to it; the upper rests on the lower, and thus both wire and web of paper pass through between them, receiving a gentle pressure, which renders the paper still more compact.

At this point the paper leaves the wire, and is received on a soft woollen blanket, or endless web of felt, which revolves continuously on rollers, and is about twenty feet in length. This endless web carries the paper between two heavy iron rollers, called press rolls, which still expel a large quantity of water. The paper can now bear its own weight, and may be handled gently without injury.

Steam Drying.—For many years after the introduction of the paper machine, the paper, after passing through the press rolls, was wound on reels, cut into sheets by hand, and then hung up in the loft to dry. But in 1821 a very useful improvement was added to the machine by T. B. CROMPTON, who invented and patented a new mode of drying by heated cylinders, and a cloth or felt. According to Mr. HERRING, the

first experiment for drying paper by means of heated cylinders was made at GELLIBRAND'S calico-printing factory, near Stepney, a reel of paper in a moist state having been conveyed thither from Dartford in a post-chaise. The experiment, which was made in the presence of the patentees of the paper machine and Mr. DONKIN the engineer, proved highly satisfactory; and the adoption of copper cylinders heated by steam was thenceforth considered indispensable. But copper cylinders were soon superseded by cast-iron ones. The former, being thin, did not retain the heat any length of time, and were rapidly heated or cooled by the least variation of pressure on the steam. The cast-iron drying cylinders at present used are made thicker, and although not so quickly heated, retain their heat longer; while any irregularity in the pressure or temperature of the steam does not so easily affect them. The number of cylinders in a machine varies from three to fourteen; they may be placed in a great many different ways, and are used of different sizes. But the best way to arrange them, is to set them in pairs, one over the other, leaving a few inches between the two surfaces.

The paper, after passing through the press rolls, and thereby parting with a quantity of water, is much firmer; but from the circumstance that the pressure on one side is exerted against the felt, it is rougher on that side than on the other; and to equalize the sides a second pair of press rolls and a short felt have been introduced. The paper passes from the first pair of rolls, presenting its rough surface to the smooth roll. It then passes on to the first drying cylinder, which should only be slightly heated; the second is heated a little more, and so on, each of the series of cylinders successively increasing in heat. By this means the paper is dried gradually, and is found to be much stronger when dried in this way than when passed over one or two very hot cylinders.

Papermakers have paid too little attention to the drying power of their machines; and in many places, while the speed of the machine has been greatly increased, the number of drying cylinders has remained the same; consequently, a great degree of heat has to be kept up, while the paper, nevertheless, is not so well dried; and in making printing paper, or paper sized in the engine, this high temperature and its quick application cause a great quantity of size to evaporate, leaving the paper imperfectly sized. Enterprising and scientific papermakers have now remedied this defect by increasing the number of their cylinders. Over a few of the cylinders is a felt web, which revolves with the cylinder, and the paper runs between cylinder and felt. The object of the felt is to dry the paper equally, and keep it from *cockling*.

In well-arranged mills, the cylinders are differently adjusted on machines for making writing and those for making printing papers. On a writing paper machine, the paper is only passed over a number of cylinders to dry it, then wound on reels. On machines for making printing paper, the paper passes over three or four cylinders, then between a pair of smooth, well-polished metal rolls, to give it a surface, and which is best done when the paper is a little moist; from these,

Fig. 382.

called *nipping rolls*, the paper passes over three or four additional cylinders.

Calendering.—The paper is now thoroughly dry, and from the last drying cylinder it passes through between one or two sets of calender rolls, to bring up the surface required. These calender rolls are often five in number—one large roll, with four small ones placed above it. The paper passing in at the top circulates to the bottom, and thence proceeds to the reel, on which it is wound. These rolls are very difficult to keep in order, and are giving place to another arrangement, which consists of two or three pairs of rolls, with springs on the top of the bearings of the uppermost roll. The rolls are placed in sets; two rolls in a set, and three sets on a machine, thereby bringing up a fine surface.

Having thus described the several parts of the paper machine, and followed the course of the paper from its first appearance in the shape of unsightly rags until it is wound on the reel, it will be necessary to add a connected and complete view of the entire mechanism, to render it thoroughly intelligible to the reader. With this view, the Editor gives in Fig. 382 an engraving of one of the most improved paper machines, recently designed and erected by Mr. GEORGE BERTRAM of Edinburgh, who is known throughout Europe for the durability and excellence of his paper machinery. Machines from his establishment are working in Sweden and Russia, as well as in all parts of Great Britain. In this figure, A denotes the pulp chest; B, valve for regulating the supply of pulp; C, spout for conveying pulp to strainer; D, strainer; E, pipe for conveying pulp from strainer to vat; F, vat; G G, small agitators for keeping the pulp of equal thickness; H H H, rolls for wire revolving on; I I I, small tube rolls for supporting wire; J J J, deckel frame with pulleys for regulating width of paper; K, deckel strap; L L, pump boxes between which the dandy roll is placed; M M, couch rolls; N N, first and second press rolls; O, rolls for felt revolving on; P, drying cylinders; R, nipping rolls; S, guide frame for dry felt; T, calender rolls for improving surface; V, reel filling with paper, and reel full.

Laid Paper and Water-mark.—When the machine was invented, only wove paper could be made by it, and it was then supposed that it would never be possible to make laid paper by it, or introduce a water-mark; but the invention of the dandy roll and pump box have removed this supposed insurmountable difficulty. It has been already stated, that when the wire passes over the pump box a large quantity of water is immediately extracted from the pulp. This gives it such a degree of consistency that any impression made on it at this point remains, owing to its passing instantly from a partially fluid state to one of greater consistency.

A dandy designed to make laid paper is covered with fine wire, laid longitudinally, leaving very small spaces between the wires. When a water-mark is required, whether a name or device, the figure or letters are made of fine wire and sewed on the surface of the dandy roll.

CUTTING MACHINE.—Previous to the introduction of cutting machines, the paper was uniformly wound on a reel, the diameter of which could be diminished

or enlarged, according to the size of sheet required. When the reel was filled, an empty one was put on, and the paper was cut off the full reel by the hand. This method of cutting occasioned a great deal of waste; many attempts were therefore made to produce a machine which would cut the paper into sheets as it issued from the machine, or as it was wound off a reel; but most of the plans, after repeated trials had been made and considerable cost incurred, were laid aside as impracticable. Mr. J. B. CROMPTON of England appears to have been the first who produced a really useful cutting machine. About 1821 he secured a patent for cutting paper into suitable lengths by a pair of shears, as it issued from the machine; and in 1828 he again obtained a patent for cutting paper lengthwise by revolving circular blades fixed on a roller parallel to a cylinder. Finally, in 1849, AMOS and CLARK patented a cutter which obviated the difficulty that arose from the constantly increasing velocity of machines, causing the sheets to be cut into irregular lengths; and this cutter is the best yet in use.

The first operation of this cutter is to cut the paper lengthwise into such widths as may be required. To effect this object, there are placed across the machine two shafts, armed with circular blades, which may be moved along the shafts to adjust them to any required width. These knives revolve at a much greater speed than the paper, which, as it issues from the making machine, or is wound off the reel, passes between the two shafts, and is cut by the knives very exactly. It may be stated that the knife on the upper shaft is larger in diameter than that on the lower, and as they revolve in contact, the action produced is similar to that of a pair of scissors.

The web being thus cut lengthwise, proceeds over a large drum for the purpose of being cut across into the lengths required for the sheets. From the velocity with which the paper travels, this is a difficult operation, and requires the paper to be momentarily arrested in its course, at regular intervals, to admit of the sheet being cut square. With this view, the drum is so contrived as to have an alternating motion; at one time bringing the paper forward the required length, and then returning. This effect is produced by a crank arm, which can be adjusted at pleasure to regulate the length of the sheet. In front of this drum, at the point where the paper leaves it, is placed a solid board or wooden block, over which is suspended a movable board or presser. The paper passes between these, and when the drum has brought forward the required length of sheet, the presser, by a particular movement, is made to descend against the block, and holds the paper fast, while at the same instant a combined motion of rolls and levers brings a movable knife against a fixed knife, and the paper is cut in the same manner as by a pair of shears. The sheets immediately on being cut are caught by boys, and laid straight in handfals. The drum, after bringing forward the required length, immediately retrogrades, while the pressers prevent the paper from being pulled back along with it. Three rolls covered with felt are placed on the top of the drum to assist in bringing forward the paper, and the moment it is held fast in the

pressers these rolls are raised by a lever and connecting rods, so that the paper is left loose on the drum, which by this arrangement can turn back without dragging the paper. The latter is continuously passing between the knives, and while the drum is making its backward motion, a *dancing roll* takes up the slack of the paper.

This cutter is invaluable in cutting laid paper on which is a water-mark. As this water-mark requires to be in the centre, from which it sometimes deviates, a portion of the machinery can at any time be stopped by hand, and a small part of the sheet cut off, thereby bringing the water-mark again to its proper place.

In addition to the cutter just described, and which is certainly the best in use for cutting paper with water-mark, there is another which also has its advantages, and of which the annexed engraving—Fig. 383—has been kindly furnished by Mr. GEORGE BERTRAM. This machine is generally used for cutting wove paper, printing paper, and newspapers, and cuts six webs at once. Six reels turn on bearings in a frame, and the web from each, passing round a smaller roller, is received

Fig. 383.

on a small drum. All the six webs, passing round this drum, are collected on a pair of small rollers, called *gathering rolls*, and by these they are simultaneously subjected to the action of the circular knives, which cut the paper lengthwise, forming the required width of sheet. By a wheel and lever, which regulate the motion, the requisite length of paper is then brought under a movable upright knife, which immediately descends on a fixed or bed knife, and severs the sheets from the webs. The sheets are then carried forward on a revolving apron to boys, who pile them carefully in handfuls; after which the paper is taken to be overlooked and finished. This description will be easily understood by the figure, in which A represents the six reels of paper on cutter frame; B, gathering rolls; C, circular knives for cutting paper longitudinally; D, feeding rolls; E, movable and fixed knives for cutting paper from web, usually called *cross-cutting knife*; F, endless apron for carrying paper to boys. This cutter has the advantage of being capable of performing about double the work of the one previously described, and is therefore used in mills where the water-mark is not put on paper.

SIZING.—Inferior sorts of writing paper, and all continental writing paper, are sized in the pulp, by the same method as printing paper; but to produce a good writing paper, it is necessary to size it with animal size after it is made.

Size is generally made at the mill from the parings of skins, called *scrolls*. Formerly the scrolls were boiled until the gelatin they contain was extracted, but the size had often a turbid appearance, and injured the color of the paper. About 1840, the Messrs. PIRIE of Stoneywood, Aberdeen, obtained a patent for an improved method of making size. Their process consists in steeping the scrolls in stagnant water until putrefaction has commenced; the scrolls are then beaten with a mallet, well cleansed, and steeped in water strongly impregnated with sulphurous acid, which acid has the property of both arresting putrefaction and bleaching the scrolls. By this process the gelatin is much more easily extracted, and the scrolls do not require to be boiled. They are put into a large wooden vessel or tub, which is set inside a cast-iron one, and between the sides of these vessels there is a space of about one inch all round. This space is filled with water, into which steam is admitted, and by the heat thus communicated the gelatin is extracted; but unless the heat is kept considerably below the boiling point the size will not be pure. When drawn off, a quantity of alum is dissolved among it for the purpose of preserving it. By this method a fine pure size is obtained, which does not injure the color of the paper; but the process is complicated, and the gelatin contained in the scrolls is liable to be injured by allowing putrefaction to proceed too far when the scrolls are being steeped. It has now, however, been found that a part of this process may be omitted, and that copper instead of wooden vessels may be used without detriment to the size.

The sizing of paper by hand-dipping was a tedious process, and occasioned a great deal of waste. Many attempts were therefore made to size it in the web, which for a considerable time were unsuccessful. About 1840 several mills succeeded in attaining this object, but with some little diversity in their methods. The mode adopted by Messrs. ALEXANDER COWAN and SONS at their mills, is to pass the paper over two rolls, about a foot in diameter, half immersed in size. Behind these rolls is a frame fitted with small rolls set at an angle. Paper, when undergoing the process of wetting, expands considerably, and these rolls have the effect of keeping the web of paper stretched to its full width, thereby preventing it from getting into creases as it passes to the press rolls, where the superfluous size is pressed out. Another and simpler method is to pass it under a drum about two feet diameter, half immersed in size, and then forward to the press rolls.

The sizing of paper is an important but difficult process. If the paper is very porous, it is also generally weak, and then the sizing occasions a good deal of waste. If again the paper has been blued with ultramarine, a strong and offensive smell is often communicated to it. The best remedy for this is to use a size which has not been long kept, to allow the paper to lie some time after being made, and after sizing to dry as quickly and as perfectly as possible. If it still retains any offensive smell, this may be partially removed by hanging it up in a place where it can be exposed to a very dry atmosphere.

DRYING.—Manufacturers having succeeded in sizing in the web, the next desideratum was also to dry it in

the same form, which, after many unsuccessful attempts, was accomplished.

The drying machine is a large frame of cast-iron, about ninety feet long and nine wide. In this frame are laid two and sometimes three tiers of skeleton drums or cylinders, three feet in diameter. A shaft passes through the centre of each drum, and to the shaft inside of the drum are fixed two arms called fans. The shaft is driven by a separate arrangement of the machinery, and is independent of the motion of the drum. The paper travels over the drum at the rate of from forty to sixty feet per minute, while the shaft is making about one hundred and eighty revolutions per minute, thereby producing a considerable agitation in the atmosphere around the dryer. Six sets of narrow bands, about one inch wide, pass over the drums from end to end of the dryer, for the purpose of conveying the paper from one drum to another. In some mills the paper passes at once from the sizer over the dryer; but generally it is wound on a reel at the sizer, and allowed to stand a few hours until the paper has cooled a little, and absorbed the size which is lying on the surface when it comes from the sizer. To convey the paper over the drying drums the end of the web is placed between the bands—three of the sets being above the paper and three below. It generally takes about fifteen minutes to travel over the dryer, and by the time it has reached the opposite end it should be quite dry and ready for the cutter.

Fig. 384 is a sectional view of the sizing and drying apparatus, where A represents the reel of paper to be

Fig. 384.

sized; B, the size cisterns and press rolls; C, drying drums with fans inside; D, dried reel of paper; E, heating apparatus; F, ventilator.

The drying machine is of great advantage to the paper manufacturer in regard to economy of time, but not otherwise. Paper when drying has a natural tendency to contract, and this is counteracted by the tension at which it must be kept when drying on the machine. Paper so dried is, therefore, not so tough as it would have been by the old method of hanging it on ropes. To meet this defect a much stronger size has to be used.

FINISHING.—The finishing, or smoothing the surface of printing paper, is now performed at the machine. After it is cut it does not require much labor. The first process is overhauling or overlooking. This is done by women, who turn over and examine every sheet, and lay aside all that are imperfect, or which have any small defect; these are called *retree*. Sheets seriously damaged are called *broken*, and when sold bring about half the price of sound sheets. The paper

is then counted into *quires*, each quire consisting of twenty-four sheets; and twenty quires, or four hundred and eighty sheets, constitute a *ream* of printing, wrapping, and colored paper. The reams are then subjected to heavy pressure before being put into covers. An excise label is pasted on the cover of every ream, and in this form it is set aside until wanted for the market.

Before being sent from the mill the excise-officer weighs the paper and writes the weight on it. He also requires the manufacturer to write or print the weight on each ream, and to put a progressive number on each. He further compares the weight on the ream with the gross weight, and if it exceeds or falls below the allowed per-centage, the paper is liable to be confiscated. Formerly the law required paper to stand twenty-four hours after being charged with duty; but this is now modified, and by complying with certain regulations paper may now be sent off a few hours after being charged with duty.

In finishing writing paper, a large amount of both labor and machinery is required. After it comes from the cutter it is pressed in strong hydraulic presses, and then rolled or glazed. The operation of rolling and glazing consists in subjecting the paper to a heavy pressure between highly-polished sheets of copper or brass. This part of the work is chiefly performed by women, who take one sheet of copper and another of paper, alternately, until they have about forty of each, which is called a *handful*. This quantity is then passed between a pair of rollers about fourteen inches diameter, set in a strong iron frame, and driven by steam or water power, working under a pressure of upwards of twenty tons. When the handful has passed through the rollers, the machinery is so constructed that the motion can be reversed, and by this means the handful is made to pass forwards and backwards several times, according to the smoothness or gloss of surface required. Highly-finished paper called *glazed*, and sometimes known as *satín* paper, is produced by simply repeating or prolonging this operation until the desired finish is obtained. To the manufacturer it is a somewhat costly process; for besides the expense of labor, which is considerable, injury to some of the paper is unavoidable, and the smallest flaw or speck in the sheets is brought strongly out by the high finish. It is evident, therefore, that writing paper which has to be highly finished, requires great care both in the preparation of the pulp, and in the manufacture of the paper.

The smoothing or finishing of the surface was formerly accomplished by placing the sheets of paper between glazed pasteboards. The boards, intermixed at intervals with *heated* iron plates, were then put into a press and subjected to heavy pressure—a process which is well known by the name of *hot-pressing*. It was very beneficial to the paper, as it took out any superfluous moisture, and made it handle firmly.

After the surface is smoothed, writing paper goes through the same process as that intended for printing, so far as regards the overhauling and making into reams. The standard quantity in a ream of printing paper is four hundred and eighty sheets, but paper is often put up with five hundred sheets in the ream, and

sometimes five hundred and sixteen, and also five hundred and twenty-eight, but in all these cases the number of sheets must be marked on the ream. The standard quantity for a ream of writing paper is four hundred and thirty-two sheets of whole, and forty sheets of broken, twenty of which must be above and below the whole.

VARIETIES OF PAPER.—The name *paper* comprehends a great number of kinds, differing very widely both in the mode of manufacture and in the purposes to which they are applied. They may, however, be all classed under four heads, namely, white paper, grey and brown paper, colored paper, and pasteboards of all kinds.

White paper includes two kinds, writing and printing, and of these there are various qualities. *Writing paper* stands at the head of this class, and the best quality is of a pure uniform color, strongly sized, and highly finished. There are many sorts of writing papers; but it will be sufficient to enumerate such of them as are best known by name to those who are unacquainted with the trade—such as cream, blue, and yellow, in color; laid and wove, in texture.

Cream is as nearly as possible a pure white. Writing shows always to most advantage on this color; but it has the defect of being more transparent than any other hue; and the high finish generally put on it increases the transparency. A small quantity of ultramarine and rose-pink improves the purity of this tint.

Blue is a fine shade, and has not the defect of transparency. It was formerly obtained by mixing a quantity of smalt with the pulp; but since the introduction of ultramarine smalt is not much used; ultramarine gives a much finer color, and is not so costly; and except in the sizing, where it occasionally causes some inconvenience, there is now no difficulty in employing it. When put among the pulp, both it and rose-pink should be well mixed in hot water, and strained twice either through a serge bag or the finest wire sieve, and should be put into the engine as soon as the chlorine is neutralized.

Yellow is simply a bluish shade given by using a smaller quantity of ultramarine than for blue; generally about a fourth or fifth part.

The old names given to paper are still retained, and also the sizes; but as the machine can make paper of any length, printing paper is generally cut to whatever size is most suitable for the printer.

The kinds of grey and brown paper used for wrapping are extremely numerous, and the varieties of colored paper are almost endless; but further details would be tedious to the reader, and would occupy too much space.

Formerly, paper manufacturers put a device, called the water-mark, on all their paper, and the old names, some of which are rather odd, are supposed to be derived from these devices. A jug or pot was put on paper of a small size; hence it still retains the name of *pott*. The fool's cap-and-bells was also one of their devices, and, although another mark has long been substituted, paper of that size also retains the name of *foolscap*. In like manner, *post* is supposed to have

been so called from the post-horn, which was at one time a common device. Besides these there were a great variety of marks, many of them of a fanciful kind, but which are now only interesting to the antiquarian.

Water-marks have frequently been of essential service as the means of detecting frauds in dating deeds, *et cetera*; and they are very useful on bank notes, cheques, and receipts. Those who are curious on this subject will find some amusing information in Mr. HERRING's work on papermaking.

The following is a list of sizes of writing and printing paper. In a few cases there are two sizes in use, and both are given:—

	Inches.
Pott,	12½ by 15
Foolscap,	17 by 13½
Foolscap—writing,	16½ by 13½
Post,	18¾ by 15½ or 19 by 15½
Copy,	20 by 16
Large post,	20¾ by 16½
Medium post,	18 by 23 or 18 by 22½
Sheet and third foolscap, ..	24½ by 13½ or 22 by 13½
Sheet and half foolscap, ..	13½ by 25
Double foolscap—printing, ..	27 by 17
Double foolscap—writing, ..	16½ by 27
Double pott,	15 by 25
Double post,	30½ by 19
Double crown,	20 by 30
Demy—writing,	20 by 15
Demy—printing,	17½ by 22½
Medium demy,	22 by 17½
Medium demy—printing, ..	23 by 18½
Royal—writing,	24 by 19
Royal—printing,	20 by 25
Super-royal—writing,	27 by 19
Super-royal—printing,	21 by 17
Imperial,	30 by 22 or 30½ by 22
Elephant,	28 by 23
Atlas,	34 by 26
Columber,	34½ by 23½
Double elephant,	26¾ by 40
Antiquarian,	53 by 31

The following is a list of coarse papers, such as grey and brown:—

	Inches.
Tient cap,	21 by 18
Bag cap,	19½ by 24
Havon cap,	21 by 26
Imperial cap,	22 by 19
Double two pounds,	17 by 24
Double four pounds,	21 by 30
Double six pounds,	19 by 28
Middle hand,	22 by 16
Lumber hand,	19½ by 29

Of purples there are—

Copy loaf,	16¾ by 21¾
Powder loaf,	18 by 26
Double loaf,	16½ by 23
Single loaf,	21½ by 27
Lump,	23 by 33
Hanbro,	16½ by 23
Titler,	29 by 35
Prussian, or double lump, ..	32 by 42

PAPER DUTY.—It would be out of place here to enter largely into the duty levied on paper; but any article on papermaking would be incomplete without some notice of it. It is usual to commence remarks on this subject by describing the annoyance and hindrance which the collection of this duty imposes on the paper manufacturer. On this point the Editor will not enlarge. The Honorable Board of Inland Revenue has for some years shown a more favorable disposition towards manufacturers than formerly; and has removed

and modified all restrictions complained of, so far as is consistent with the collection of the revenue and the protection of the honest trader. The officers of excise, also, generally give every facility in their power, and accommodate the manufacturer so far as their duty will permit. But the labor and much of the annoyance caused by the collection of this duty can only be removed by its total repeal.

This tax was first imposed in the year 1711. The law imposing it, and the regulations for its collection, have undergone many changes and alterations, which it is not necessary to particularize. When the duty was first imposed it was easily and to a great extent evaded; and manufacturers were not over scrupulous about the means of doing so. This naturally created a good deal of bad feeling between the manufacturers and those officers who acted honestly in the discharge of their duties. The expedients to which many manufacturers in former times resorted, and the indirect bribes which were given to excise officers, form a dark page in the history of papermaking; and it is a somewhat remarkable fact, that all those who resorted to these unworthy expedients have been ruined, and nearly all have been driven from the trade.

About the year 1800, the laws imposing the duty were revised, and paper was divided into three classes:—The first class comprised all paper made from rags, the duty on which was threepence per pound; the other two classes comprised all paper made from tarred ropes and all pasteboards, the duty on which was three halfpence per pound. In 1836 these laws were again revised; the division of paper into classes ceased, and a uniform duty of three halfpence per pound was imposed. A few years after this five per cent. was added to the duty; and under these laws the tax is still levied. This addition of five per cent. on the duty has been a heavier burden on paper manufacturers, and has been more complained of than the duty itself. It is a well-known fact that no corresponding advance was obtained upon the price of paper at that time. The additional five per cent. was, therefore, virtually a direct tax on paper manufacturers; and to show that this is not a mere trifle about which there should be no complaint, it may be stated that at a moderate computation a paper machine makes annually about seven hundred and fifty thousand pounds of paper, the duty on which is upwards of four thousand six hundred pounds sterling; and five per cent. on this sum amounts to upwards of two hundred and thirty pounds sterling. But with the exception of this sum the duty on paper is a burden on the consumer; and were the community alive to its baneful effect in diminishing the demand for labor it would have been repealed long ago. The Editor believes that all politicians now admit the impropriety of taxing the raw material of any manufacture. But paper is the raw material upon which a large portion of the population of the country is employed. Were it possible to trace it from the time it was a piece of dirty rag until it appeared as a highly-finished book, or an ornamented piece of papier maché, or an embossed envelope, it would be found very difficult to name any other material on which a greater amount of labor is bestowed.

The Editor conceives he is warranted in assuming that the repeal of the duty would greatly increase the consumption of paper, from the fact that the trade doubled itself in fourteen years after the duty was reduced to three halfpence per pound. This reduction took place, as already stated, in 1836. Now, in 1835, duty was paid on seventy million, six hundred and fifty-five thousand, two hundred and eighty-seven pounds; in 1850, on one hundred and forty-one million, thirty-two thousand, four hundred and seventy-four pounds—a great impetus having been given to the publishing trade, and to all those manufactures in which paper is used, which undoubtedly contributed to the prosperity of the country; nor should the fact be overlooked, that the reduction of the duty brought the means of obtaining useful information and rational enjoyment within the reach of the humblest classes of the community.

But, like all other evils, this duty has found defenders. One of the most plausible of their arguments is, that the excise regulations—which require that the weight to within five per cent. on paper above twenty pounds, and to within ten per cent. on paper below twenty pounds per ream, be written or printed on each ream—*gives security to the purchaser that he is not imposed on by a false weight.* One would suppose that a ream of paper could be weighed as easily as any other article, and any fraud of the kind at once detected. But the argument is altogether fallacious. Paper is sold not by the weight marked on the ream, but by the real weight; and if it exceeds the required weight, paper manufacturers lose the excess, and this is to them a source of considerable loss.

Another objection urged to the repeal of the duty is this—it is so small that its repeal would benefit only the paper manufacturers and printers, while the community generally would never derive any advantage from it. Let it be admitted that it would be a boon to papermakers and printers—it might be supposed that this would be an argument for and not against the repeal. It is difficult to see any justice in subjecting these classes in particular to an onerous burden, to which other merchants and manufacturers are not liable; and although the repeal of the tax would not lessen the expenditure of those who buy few books and no paper, yet even they and the entire community would be benefited by the increased demand for labor which would undoubtedly follow the extinction of this most impolitic impost.

STATISTICS.—IMPORTANCE OF THE PAPER TRADE.—The introduction of FOURDRINIER'S machine, and the application of steam power, with other improvements, have effected a complete revolution in the art of making paper, and have placed the trade among the staple manufactures of the United Kingdom.

Formerly paper-mills were spread nearly over the whole country, especially in England. Wherever there was a good stream of water, a paper mill was almost invariably to be found. These mills were generally small; *one machine will now make as much in one hour as some of them made in a day.* At that time, too, the trade was in the hands of a few wealthy firms, chiefly located in London, on whom paper manufacturers were to a great extent dependent. The exten-

sion of the trade, and the large amount of capital now invested in it, have to a considerable extent broken up that system; and the Editor believes that the firm of ALEXANDER COWAN and SONS, Valleyfield Mills, where the paper on which this work is printed is manufactured, was the first to adopt means to free itself from this virtual monopoly. In the year 1810 their mill there was one of the largest in Scotland, yet there was not produced then more than one thousand pounds of paper per day, or about fifty reams, whereas above four hundred reams are now made, the half of which is highly-finished writing paper. Some idea of the extent of these works may be formed from the fact, that there is made at an average every day forty miles of paper, five feet wide, or as much as would cover above twenty-four acres. The space required for finishing the paper covers nearly one thousand three hundred square yards, or something more than one-third of an acre, and above seven hundred people are employed.

There has, perhaps, in no locality been a greater extension of the trade than on the river Esk, on which these mills are situated. At the close of the French war, in the year 1815, twenty-six vats were in operation, the produce of which would not exceed four thousand five hundred pounds of paper per day, and the number of people employed could not be more than four hundred; there are now on that river fifteen

machines at work, the produce of which is not less than thirty thousand pounds per day, and the number of people employed amounts to about two thousand.

The subjoined statement, derived from sources of undoubted veracity, will show the extension of the trade generally. In the year 1784 the value of paper made in the country was estimated at eight hundred thousand pounds, the duty on which was forty-six thousand eight hundred and sixty-seven pounds sterling; in the year 1856 there were charged with duty, one hundred and eighty-seven millions, seven hundred and sixteen thousand, five hundred and seventy-five pounds sterling. The duty on this would amount to one million, two hundred and thirty-one thousand, eight hundred and eighty-nine pounds; assuming the value of paper at an average to be about three times the amount of duty, the value charged with duty in that year would amount to three millions, six hundred and ninety-three thousand, six hundred and sixty-seven pounds sterling. The number of people employed in the direct manufacture of paper is supposed to be about thirty thousand; but, besides this, there are thousands who find occupation in making and repairing the machinery used, and also in preparing the chemical substances required in the manufacture.

The annexed table exhibits the quantity of paper in the United Kingdom charged with duty, exported, and retained for home consumption during ten years:—

	1847. Pounds.	1848. Pounds.	1849. Pounds.	1850. Pounds.	1851. Pounds.
Charged with duty,	121,965,315	121,820,229	132,132,660	141,032,674	150,903,543
Exported,	5,852,979	5,180,286	5,966,319	7,762,686	8,305,590
Home consumption,	116,902,336	116,639,943	126,166,341	133,269,988	142,597,943

	1852. Pounds.	1853. Pounds.	1854. Pounds.	1855. Pounds.	1856. Pounds.
Charged with duty,	154,469,211	177,633,009	177,896,224	166,776,234	187,716,575
Exported,	7,328,886	13,296,874	16,112,020	11,110,924	14,798,979
Home consumption,	14,710,325	164,336,135	161,784,204	155,665,310	172,917,596

The following table shows the quantity of paper charged with duty in England, Scotland, and Ireland,

respectively, during the years 1855, 1856, and nine months of 1857:—

	1855.	1856.	Nine months of 1857.
England,	123,552,869	139,752,062	109,660,884
Scotland,	35,932,985	40,100,234	31,925,920
Ireland,	7,290,380	7,864,279	6,081,269
Total,	166,776,234	187,716,575	147,668,073

These figures prove the expansion of which the trade is capable; but however important the paper manufacture may be as a source of national industry, it is justly entitled to a higher place than that which belongs to it merely in this material aspect. There is no article so intimately connected with *mind* as paper—none upon which the development of the moral and intellectual nature of man is so dependent; and mankind is now learning how much the welfare of the race depends on the right cultivation of the mind. It is now universally admitted that in a densely-populated country there is no permanent security for life, property, and progress, unless the whole mass of society is leavened with the rudiments of knowledge and the principles of morality. For this purpose paper is essentially requisite. It would be vain to speculate with regard to the future, but it is evident that paper must

be the medium of diffusing the blessings of knowledge and Christianity throughout the world, and is destined to be one of the most powerful agents, under Divine Providence, in renovating the human family.

PERFUMERY.—*Parfumerie*, French; *parfümerien*, German.

By nature's swift and secret working hand
The garden glows, and fills the liberal air
With lavish odors.—*Thomson*.

The distinction between perfume and odor is substantial as well as critical—the former designating those volatile emanations which are usually considered agreeable, while the latter, in its general signification, is applicable to every scent, irrespective of its nature. GREMIO, in *The Taming of the Shrew*, directs that the papers he sends to BIANCA may be *well perfumed*, for she is *sweeter than perfume itself*; while, in *King John*,

SHAKSPERE makes CONSTANCE call death *thou odorous stench*. Of the five senses, that of smelling is the least valued, and, as a consequence, is the least tutored; but from this one must not conclude that it is of insignificant importance to the welfare and happiness of mankind.

By neglecting to tutor the olfactory nerve, one is constantly led to breathe vitiated air, and thus poison the body by neglecting the warning given at the gate of the lungs. Persons using perfumes are more sensitive to the existence of a vitiated atmosphere than those who consider the faculty of smelling as an almost useless gift.

HISTORICAL NOTICE.—There is no delicate luxury which has held its influence so long and so uninterruptedly upon refined society as that of perfumes; and their annals comprise the history of the folly, voluptuousness, and extravagance of past ages. The antiquity of their use is very great, and one is almost lost in searching for their origin.

Perfumes seem to have been first imported from Elam, now called Persia, and they were important articles of commerce between that country and Egypt. The distant deserts were often traversed by camels laden with *odors of sweet scents*; and when the Ishmaelitic merchants, to whom JOSEPH was sold, were going to Egypt, they were wending their way with *spices and balm and myrrh*. At a later period, but long before the time of CONSTANTINE, the Turks were accustomed to lubricate their persons with fragrant unctions, to complete the gratefulness and value of their baths. MOSES was commanded to speak unto the children of Israel, that in the offerings of the tabernacle they should bring *sweet spices, and anointing oil, with sweet incense*; and that they should make of the former *a perfume, a confection after the art of the apothecary, tempered together, pure and holy*.

Indeed, perfumes were considered among most of the ancients as necessities of life, and entered into nearly all their ceremonies of a religious or social nature. They were used both at feasts and at funerals, and were burned as well in honor of the living as of the dead. The priests of Memphis offered them as incense, daily, to the sun; and the Egyptians, by their aid and with resins, have transmitted their illustrious dead, in mummies, through thousands of years to living generations.

As in the Mosaic days, spices and frankincense were held as sacred offerings to the Lord of Hosts, so in the new era of religion the practice was not discontinued, and CHRIST after crucifixion was embalmed in spices; but at first, it seems, that certain spices were devoted only to religious uses, for EZEKIEL accused the Jews of profanity in applying to their own purposes the odors which were reserved for sacred things; and ISAIAH reproaches them as faithless to God, and as like a spouse painted and perfumed to please strangers.

The present mode of introducing flowers at repasts was common among the Grecians and Romans. Rich perfumes and precious ointments were among the treasures found by ALEXANDER in the camp of DARIUS, and thus, possibly, the Greeks borrowed the example of their use from the Persians. The violet was most grateful to the Athenian taste, but every part of the

body had its appropriate perfume; the oil extracted from the palm was thought best adapted to the cheeks and the breasts; the arms were refreshed with balsam mint; sweet marjoram supplied an oil for the hair and eyebrows; and wild thyme for the knee and neck. Perfumes, in time, became very common among them. The *nardus* and *malobathrum* were held in much estimation, and were imported from Syria. The *baccaris*, the *brenthium*, the *psagda*, the *plangonium*, and the *sagdas*, made principally of the general constituent of all the ancient ointments, *videlicet*, myrrh, had their respective eulogists. The saloon, where any entertainment was given, was generally perfumed by burning myrrh or frankincense in it. A nice distinction divided perfumes into two kinds: the first were of a thicker sort, and applied more as salves, or wax; the latter were liquid, and poured over the limbs. To indulge in the liquid ointment was considered as effeminate and voluptuous, but the sober and the virtuous were permitted to use the thicker variety without any impeachment of their good qualities. The supplies of perfumery occupied a considerable place in the stock of those artisans who contributed to the embellishment of a Grecian lady of fashion. The article itself bore a high price, but this did not hinder voluptuaries using it profusely, not, however, without an occasional admonition from the grave men of the mischief arising from its abuse. The old people referred to a statute of SOLON, forbidding the sale of perfumery, at least by the male sex; SOPHOCLES significantly described VENUS as sprinkled with perfume, and looking in a mirror; and PALLAS, the goddess of wisdom, as moist with olive oil, and practising the exercises of the palaestra. SOCRATES objected to the use of perfumery altogether. There is the same smell, said he, in a gentleman and a slave, when both are perfumed. In his opinion, the only odors worth cultivating were those arising from honorable toils and the smell of gentility.

A knowledge of perfumes soon extended from Greece to Rome; and the abuse in the employment of them was such that PLINY lamented their introduction into the camp. NERO is said to have consumed in the funeral pile of his wife, POPPÆA, more incense than could have been produced from the whole of Arabia in a year; and under the consulate of SUCINIUS CRASSUS, in order to secure a sufficiency for church purposes, a law was necessary to restrict the use of them to that and a few other special objects.

With the decline of the Roman Empire, the European commerce in perfumery diminished; and in the disastrous epoch of Vandalism, when floods of barbarians inundated the capital of the world, refined taste took its flight, and perfumes became obsolete. In modern days, however, civilization revived, and brought back with it this one of its concomitants, which was soon nurtured into a vigorous growth, upon the institution of a new era of gallantry and elegance. The supremacy of woman's influence being thus re-established, perfumes, as aids to beauty, were in constant and extravagant demand.

In the reign of LOUIS the Fifteenth, the ladies at court indulged most freely in perfumes, and fashion ordained an ever-varying routine; so that the royal

apartments were one day fragrant with the scent of the tuberose, and the next with that of amber and cloves; and so on, consecutively, each succeeding day bringing a change of the reigning odor. In that luxurious age, the personal use of perfumes was not confined to the fair sex, but the effeminate gallants and *petit-maitres* of the day gloried in perfuming themselves with the favorite scents of their mistresses or of presiding belles; so that allegiance was recognized, not, as in more chivalrous times, by the knight wearing the colors of the fair one who had enslaved him, but by his smelling of the particular odor which she had consecrated to herself.

Pathologically considered, the use of perfumes is in the most eminent degree prophylactic; the refreshing qualities of the citrine odors to an invalid is well known. Health has often been restored when life and death trembled in the balance, by merely sprinkling the essence of cedrat in a sick chamber.

Throughout all civilization, from the dim early ages to the enlightened days of the present—through every ramification of society, and in all the sacred ceremonies of life—flowers and perfumes have ever borne a conspicuous part, and by their graces and freshness, touching allegories and seducing sweetness, blended themselves with the pleasures and hopes of mankind; sometimes typifying transient images, but still, *also*, appearing as the beautiful symbols of those affections and principles which are *most enduring*.

SOURCES.—Perfumes are derived from a variety of natural sources; a few being of animal origin, and the remainder emanating chiefly from the vegetal kingdom. In their primitive state of isolation, they may be termed *simple*, in contradistinction to the *compound* odors, which are made up by combinations of the former, varied according to the taste and skill of the manufacturer. In this way an infinite variety of scents may be obtained. But the art of the perfumer is not wholly restricted to the preparation of odors; it extends also to the fabrication of pomades, aromatic vinegars, washes, tooth powders, cosmetics, fine soaps, and all appliances of the toilet which by their tonic, emollient, or cleansing properties, will improve the health and beauty of the skin, hair, and teeth. In some of the preparations, certain *mineral* matters enter as ingredients to impart color or consistence; and but rarely for any purpose otherwise connected with the efficiency of the product. In all instances, however, the smell is most important. When the perfume does not exist in a free state, it is then manufactured from the raw material by mechanical or chemico-mechanical means; as, for instance, by expression, distillation, maceration, infusion, and enfleurage, as will be more fully explained hereafter in treating of the essential oils, extracts, fats, waters, *et cetera*.

In enumerating the raw materials used in the manufacture of perfumery, it will not be possible here to give more than the striking properties and characteristics of each. These will, however, suffice to convey the necessary information for making a judicious selection; and it is only necessary to add that the purity of the *stock*, and the manner in which it has been gathered and kept, have an important bearing upon the quality and quantity of the products to be obtained from it.

ANIMAL SUBSTANCES.—The *perfume*-materials of this class are only three, and each is an animal secretion: namely, musk, civet, and ambergris.

Musk.—This exists in the excretory follicle behind the navel of the adult *male* of the *moschus moschiferus*, or musk deer, of Siberia, Thibet, China, and other mountain ranges. These bags, or *Pods*, as they are termed in commerce, contain from two to three drachms of musk. When separated from the sack, it is called *grain musk*. Tongva musk outranks all others in quality, and that from Russia is the most inferior. Thibet musk is of intermediate quality. The high price of this substance renders it liable to adulteration with dried blood, brown earth, *et cetera*. The finer grades are frequently weighted by the fraudulent introduction of pieces of lead into the pods. To test the quality of musk, plunge into the pods a wire which has been rubbed with garlic, and then note the odor. If the garlic odor is disguised by the musk, the latter may be considered of good strength.

Musk, from its pleasantness and permanence, becomes a general basis-odor; and from these, and its diffusibility, it may be called the wings of the perfumes, as, besides carrying with it the other fragrances, it survives to pronounce their departure and illustrate its own durability. It requires, however, to be very much diluted, in order that it may not prevail too much in the scents which may contain it as an ingredient.

Civet.—The secretion of the civet cat, or *viverra civetta*; also, of the *viverra zibetha*. It is scraped out from the glandular receptacle near the anus, and sent to market in small bags made of the skin of the animal. The supply comes mostly from Malabar and Bassord. It is of a pale yellow color, and has a musky odor of such intensity as to be offensive, except in a highly diluted state. Its admixture in small proportions with other perfumes gives agreeable modifications, and imparts strength and permanence.

Ambergris.—So called from *amber-gris*—grey—because of its having been considered by some of vegetal origin, and analogous to amber. It is more probably a bezoar from the whale, and may be a product of disease. It is found floating on the sea, near the coasts of China, Japan, Coromandel, Brazil, Ireland, and America. It is in small irregular masses of scaly fracture and grey color, with yellow, and sometimes black streaks. It emits a very peculiar and diffusive smell of great power, and is largely used in admixture with more feeble and less persistent odors.

Spermaceti.—A beautiful, pearly-white, dry, inodorous fat, found in the bony receptacles of the head of the white whale—*physeter macrocephalus*. It is obtained by subjecting the head matter of the whale to hydraulic pressure, for the separation of the oily portion. Unless entirely freed from oil, it is liable to become rancid. It may be purified sufficiently by subjecting it repeatedly to hot pressure; or, more expensively, by dissolving out the oil with boiling alcohol. Its structure is scaly, and it may readily be crystallized in plates. When pure, it melts at 120°. *Solar spermaceti* is the popular name of an admixture of true spermaceti with palmitic acid.

Spermaceti has eminent emollient properties, and is

used in perfumery as an ingredient of pomades, creams, cosmetic pastes, and the like.

Wax.—This is the solid portion of the honeycomb, produced by the hive bee—*apis mellifica*. In its native state it is yellow, or brown-yellow, and sometimes grey; but it can be bleached perfectly white by chemical means, or by exposure, in thin ribands, to the combined action of light, air, and moisture. It is the white wax which is most generally used by the perfumer; and that bleached by the latter method is the best, as it is purer, firmer, and drier; moreover it is tasteless. Pure wax melts at 149°. It is often adulterated with earthy matters and stearic acid. The first shows itself when, on melting the wax, an infusible and insoluble substratum remains. The last is known to be present if effervescence and a gelatinous solution are produced by boiling some of the wax in distilled water, containing one-fiftieth of its weight of carbonate of soda. There are also several kinds of vegetal wax assimilating to beeswax in physical character, but they have not yet been employed in the art of the perfumer.

Suet.—As found in commerce, suet is generally a mixture of beef tallow and mutton fat. It is *rendered* by heating the *rough fat*, and pressing it, to separate the membranous matters. When of good quality it is firm, and does not melt below 98°.

Suet and lard form the body of pomades; and that the quality of these latter may be unexceptionable, the fat material must be perfectly fresh, inodorous, and pure. The rendered suet being almost always more or less deficient in those respects, it must, therefore, be subjected to a purifying process, in order to fit it for use in perfumery. This is done by melting the fat by the heat of a saline or steam bath, in an enamelled iron vessel, and adding to it, gradually, powdered alum and chloride of sodium, in the proportion of one ounce of the former, and two ounces of the latter, to every fifty pounds of fat under treatment.

The heat is to be continued above 212°, until scum ceases to rise to the surface, which contains all the organic and other impurities, and must be removed with a skimming ladle as fast as it is formed. The fat is then to be strained through bolting cloth into clean stone jars, and there left to cool. It is next to be spread upon a circular stone slab, with its top surface slanting from the centre, over which a stone roller is made to move by suitable gearing. As the roller, or muller, as it may be called, revolves over the fat, cold water is allowed to trickle upon it, and this latter acts by dissolving out the saline and organic impurities, and in flowing off carries them away. This treatment is continued until the fat is free from foreign matters, after which it is to be melted, and heated, as before, until all retained water has been expelled by evaporation. When cold, the fat will be found to be very white and pure, and in a condition to preserve its sweetness. In this deodorized state it is suitable for use with the most delicate odors. An apparatus like that described under DYEING, Vol. I., page 703, will be very suitable to carry out the process just described.

Lard.—This is the fat of the common hog, and that kind commercially known as *corn-fed lard* should be selected, as it is superior to other grades in many

respects. Though fine and white, it is softer and more fusible than suet. It melts at 81°. The lard used for perfumery should be pan-rendered, over an open fire, or by *dry steam*; for if *wet steam* is used, and under pressure, as is most generally the case, then it contains foreign organic matters in solution, which give it a tendency to decomposition, and cause it to emit a disagreeable smell. Moreover, it is then granular, instead of being smooth in body. To give it a condition suitable for the perfumer, it must, however, be carefully rendered, and undergo purification in the same manner as directed for suet.

Both lard and suet are used as *body* for pomades; the former constituting *soft body* for winter climates, and the latter *hard body* for summer temperatures.

Suet and lard are described also in Vol. I., page 413, to which the reader is referred.

Bears' Grease and Beef Marrow.—The fat of the common bear is soft, and not unpleasant in odor when carefully rendered. It is a favorite grease for the hair, and for that purpose, as well as to cheapen it, is often mixed with marrow obtained from the *marrow bones* of beef cattle.

COLORING MATTERS.—It is often desirable, as a matter of taste, to tinge these bodies; and the process to be followed for them, and also for other fats, whether solid or fluid, is as follows:—

Alkanet root is the coloring matter for imparting a *pink* shade, and four ounces are required for every pound of fat. The fat having been melted over a water bath, the bruised root is then added, and the whole digested at a moderate heat for several hours. The mixture is then strained through bolting cloth, and the clear fluid fat, now colored deep pink, allowed to cool; and this may be termed the tinctorial substance. One ounce of this highly-tinged body will suffice to impart a hue to a pound of fat; and the manipulation consists in simply melting the two together, by gentle heat, in an enamelled pot. *Yellow* coloring body is similarly made with annotta, in the proportion of one ounce to the pound of fat. To give a *green*, fresh walnut leaves may be used. A *brown* shade may be obtained by merely adding a few drops of *caramel* to the melted fat, and continuing the heat until the water which held the caramel in solution has evaporated. Color may be imparted also by the addition of pigments in powder, but these latter are objectionable for pomade body, hair oils, and creams.

Cochineal.—This is a small wrinkled insect—*coccus cacti*—indigenous to Mexico and New Spain, which feeds upon several species of cactus. After having been scraped from the leaves, it is scalded, and then dried in the sun. The best is that which presents a silvery white exterior. Cochineal gives a brilliant crimson powder, and is used in that way as a coloring matter. A *liquid scarlet* may be made from it by boiling, say one ounce in eight ounces of distilled water, for fifteen minutes, and then adding thirty grains of powdered alum, and then reboiling for three minutes, and straining through bolting cloth. *Carmine*, the brilliant red used so extensively as a finer color for rouges, powders, *et cetera*, is made from cochineal. It is soluble in aqua ammonia, and, thus treated, it forms the solution called *liquid carmine*, or carmine ink, which also has a wide

range of application in the manufacture of perfumery. Carmine is prepared on a large scale by the practical chemists, and of various qualities. French carmine is considered the best.

VEGETAL SUBSTANCES.—The art of perfumery is almost wholly dependent for its existence and success upon the botanical kingdom; as the simple odors, with very few exceptions, come exclusively from that source. The only peculiarity in this respect is, that the plants growing in tropical latitudes are more prolific in odor than those of Northern climes. The East Indies, Ceylon, Peru, and Mexico, afford rich supplies of their indigenous stock; and nearer home, the South of France, bordering on that part of the Mediterranean between Toulon and Nice, is almost entirely cultivated for the production of perfume materials. Grasse and Cannes are the two principal flower gardens; and the genial, equable climate of this region renders it peculiarly favorable for the purpose to which it is devoted. To the enterprise and skill of their inhabitants the world is indebted for many of the finest and best perfumes, and they in return derive a large revenue from the trade.

The odor of a plant is due to a highly volatile matter, which is most generally an oil, called the essence or essential oil. In some instances, however, the odor is a very delicate and ethereal principle, and, therefore, not in a tangible form, though very evident to the sense of smell. In this latter case it is extracted and fixed through the agency of a medium substance, as will be explained under the head of pomades. The odors, though every odor is not necessarily fragrant, exist already formed in the living plant, or else are generated, as in the instance of bitter almonds, by some reaction between the elements, which takes place during fermentation or distillation. It is generally secreted in little sacs or vesicles, and so well confined that it does not escape in many cases even during the drying of the plant, if it be carefully done, whilst in other plants again, the aroma is being constantly produced at the surface, and as constantly exhaled at the moment of formation. The organism of the plant, and its vital force, are the creating power.

The aroma exists in every part of plants, but not in all portions of the same plant. Sometimes it is obtained from the root or wood, then from the bark, and again from the flowers, leaves, fruit, or seeds. Some few plants yield odor in all their parts. The orange gives three distinctive odors—*oil of neroli* from the flowers; *essence of Portugal* from the rind of the fruit; and *oil of petit-grain* from the leaves; and thus it appears that the oil may also differ with the part of the plant whence it is obtained.

The resinous and balsamic exudations of plants, such as benzoin, and myrrh, and the like, are often impregnated with the aroma of the plant.

The scents of plants are extracted in the form of oils, or attars, extracts, fragrant waters, *et cetera*; and the skill and taste of the perfumer render them capable of being infinitely extended and diversified by combination. In this way the great variety of *bouquets* have their origin.

There are many substances of vegetal nature also used largely in the art of perfumery for other purposes than as scents. For obvious reasons the Editor must

restrict the notices to those which are the most important; and for the better understanding of the subject, will classify them into roots, woods, leaves and flowers, seeds, balsams and resins.

1. ROOTS.—These yield their aroma by distillation with water, in the form of essential oil, or scented waters. They may also be used in powder.

Angelica—from the garden, or *a. archangelica*. The tops of the flowers are also serviceable. The root is spindle-shaped, greyish-brown, and much wrinkled externally, and whitish and spongy within when dried. Its fragrance is due to a volatile oil.

Calamus, or *Sweet Flag*—is the root-stem of the *acorus calamus*, and comes in long, slender pieces, with a yellowish-brown and wrinkled exterior. It is white in the interior, and gives off an aromatic odor, which may be obtained in the form of volatile oil.

Ginger.—The root of the *amomum zingiber*, growing in the East and West Indies, and Mexico, enters into the combination of many aromatic waters, and several kinds of dentifrice. The *white* ginger of Jamaica is considered the best, being the selected roots deprived of their epidermis. It gives a yellowish-white powder, and emits a penetrating aromatic odor. A volatile oil may be separated by distillation, but this property is generally and more readily extracted in the form of a tincture, by macerating the root in alcohol.

Orris, or *Iris*.—The white, fleshy part of the root of the *iris florentia*, which is native to Italy, and cultivated in the South of Europe. It comes in pieces of irregular form and size, which, being brittle, are easily reduced to powder. It emits an odor assimilating to that from violets, but very much inferior. The powder enters largely into the composition of tooth and sachet powders, for the purpose of giving volume as well as odor. Its tincture, made by digesting one pound of the powder in one pint of alcohol for two weeks, and filtering, is used to give body to more feeble perfumes, and improve the fragrance of those which are deficient in that property.

Souchet.—The root of the *cyperus longus*, and emits an agreeable, violet-like odor. It is generally macerated in acetic acid, then dried and reduced to powder.

Vitiver, or *Kus-kus*.—The fleshy part of a species of dry grass from India. It has an aromatic odor, and is used in the same manner as *orris* root. The tincture or extract of *vitiver* is made by digesting one pound of the dried root in a quart of alcohol for two weeks, and filtering. This tincture was formerly much used in bouquet combinations, and was an important ingredient in the once celebrated preparations of that kind called *mousseline des Indes*, *bouquet du roi*, *et cetera*. By distillation, it yields about one per cent. of volatile oil called *otto of vitiver*, and resembling, according to PIESSE, the *otto* of santal.

2. WOODS.—Those which are used as scents yield their odors by distillation with water, or by digestion in alcohol or other solvent. They are also used in powder, and several of them merely as coloring matters.

Aloe.—There are three varieties of this wood, and all come from China; namely, first, *calambac*; second, *agalochium*; and third, *aigle* or *garc*. The first is very rare and high-priced, being used only for fumiga-

tions in temples; is brownish-red, resinous and heavy, and emits in burning an aromatic odor. The *agal-lockium* is orange-colored, has a waxy fracture, and an odor less myrrhine than the calambac. This is the kind usually found in commerce. The *aigle* or *garç* wood differs from the other two in having a greenish-yellow color and musky odor, and also in not being bitter. It is fibrous, sometimes spongy, and, when burned slowly, eliminates an agreeable aroma. The latter two are used as ingredients of fuming pastilles.

Brazil.—The chipped wood of the different species of the *casalpinia* growing in Brazil and the West Indies. That from Pernambuco is the hardest and best. When freshly cut it is light reddish-brown, but on exposure becomes of a brighter tint. It is used as a cheap tinctorial matter, and forms the material whence the lakes are made. Its color may be extracted in soluble form, by boiling four ounces of the wood in a quart of water containing one drachm of chloride of tin, and filtering.

Cascarilla.—The bark of the *c. gratissimus*, as well as that of the *c. fragrans* and *c. fragilis*, are used as ingredients of fuming pastilles. The first is a component of the *eau à bruler*, for perfuming apartments, and is the most fragrant and valuable of the three kinds. Its leaves, according to PIÈSSÈ, are gathered by the Koras of the Cape of Good Hope as a perfume.

Cassia.—The outer bark of the *cinnamomum cassia*, and the Chinese cinnamon, from Canton. It yields, by distillation, about three-fourths of one per cent. of volatile oil, of aromatic rather than flowery odor, and much used for mixing with other perfumes, and for scenting soaps.

Cedar.—The wood of the cedar emits an agreeable odor when burned, and on that account is sometimes made into sticks for lighting lamps. In a finely-ground state it may be employed as a body for sachet powders, for it is said to keep away moths. It gives on distillation a fragrant volatile oil, occasionally used for scenting toilet soaps. The wood forms a crimson-colored tincture with alcohol, and may be thus employed to tinge and scent tooth-powders.

Cinnamon.—The bark of the *laurus cinnamomum*, and that from Ceylon is the best. It is very thin, brownish-red, and has an agreeable aromatic flavor. The cassia, which it resembles closely, is thicker, rougher on the surface, and comes in larger rolls or quills. The first is often sophisticated with the latter, and sometimes even a part of its volatile oil is abstracted by infusion in alcohol. This latter fraud is detected by the feeble smell and taste of the cinnamon. The finely-ground bark is used for pastilles, sachets, and tooth-powders. Its aroma may also be extracted in the form of tincture, by alcohol. By distillation, it yields an essential oil of powerful odor, which is largely used in combination with oil of cloves and other strong essences.

Clove.—This bark, known also by the name of *cannelle giroffée*, and *bois de crabe*, is brought from the West Indies. It comes in concentric cylinders of about two feet length and an inch diameter, and has a dark-brown color. Its aromatic flavor, though similar to that of cloves, is much weaker.

Guaiacum.—This wood is imported from the West Indies. It is hard, compact, and resinous, and when burned or rubbed emits an agreeable odor. It enters into the composition of odontalgic liquors.

Rhodium.—Called also *rose wood* and *cyprus wood*; and incorrectly, by the French, *jacaranda*. It is the wood of the *convolvulus scoparius*, and has a pale-red color, and slightly bitter taste. It emits an agreeable perfume, and is used when ground for sachet powders. When distilled it yields a sweet-smelling oil, but this latter is seldom used, being superseded by the oil of geranium.

Santal.—This grows in the island of Timor and the Santal Wood Islands, and is improperly called *sandal* wood. It is extensively employed by the Brahmins, Hindoos, and Chinese, as incense in their religious ceremonies. Its strong, agreeable, and peculiar odor is very offensive to ants, and renders it a good material for cabinet ware. By distillation, it yields attar of santal, which is dense and oily, and has a dark straw color. It is often used in the form of extract, or tincture, made by dissolving one ounce of the attar in three pints of rectified alcohol, and adding four ounces of essence of rose. CAMERON writes of this scent as follows:—

The santal tree perfumes, when riven,
The axe that laid it low.

Sassafras.—The bark of the *laurus sassafras*, and is used in the form of tincture made by digesting it in alcohol. It also affords a volatile oil, but its odor is not delicate. It is employed for perfuming the coarser grades of transparent soap, and for admixture with other strong and common odors, to modify and improve their intensity.

3. LEAVES AND FLOWERS.—The leaves and flowers are when in a fresh state, of much greater advantage than after being dried. Indeed, very many are not serviceable for the extraction of their perfume, except when recently harvested. Drying is only resorted to with certain kinds for exportation, and this process must be carefully conducted in air chambers, to which the sun has access in summer. In winter, a gentle heat is necessary. The flowers or leaves are placed upon wicker waiters, and require to be stirred occasionally, in order that new drying surfaces may be presented, and fermentation hindered. In Grasse and Cannes the harvest is gathered by itinerant agents, called *commissionaires*, in the employ of the growers, and through them the product is sold to the distiller and perfumer. The harvest takes place at the flowering time of the plant, in a dry season, and towards the noon of the day, after the dew has evaporated.

Balm.—The leaves of this herb—*melisia officinalis*—yield, by distillation, a volatile essence, sometimes called the oil of melissa. It has a peculiar, fragrant odor, but is seldom used. The leaves lose their fragrance, in a great measure, when exsiccating.

Cassie.—The flowers or buds of the *acacia farnesiana* yield a very intense, but delightful odor, resembling that of violets, and much used in compounding fine scents for the handkerchief. The process of infu-

sion must be employed for its extraction and preparation. It is cultivated extensively at Cannes. DRYDEN, in his *Virgil*, thus alludes to it:—

The short narcissus and fair daffodil,
Pansies to please the sight, and *cassie* sweet to smell.

The *Wattle*, a plant of the same genus as the foregoing, and which grows luxuriantly in South Australia, yields, according to PRESSÉ, a very similar perfume.

Citron.—The flowers of this plant—*citrus medica*—give, by distillation, a fragrant oil, which is much in demand for the manufacture of Cologne-water.

Citronella.—This is supposed to be one of the grasses of the *andropogon* genus. The oil comes from Ceylon and the East Indies, and its odor resembles that of the oil of citron fruit. It is comparatively inexpensive, and forms the perfume of the so-called honey soap.

Elder.—The flowers of this plant—*sambucus nigra*—have a peculiar sweetish odor, and are used for preparing, by distillation, the elder flower-water. This latter enters into the composition of several cosmetic creams, milks, and oils.

Fennel.—The common fennel herb—*feniculum vulgare*—has an aromatic odor due to the existence of a volatile oil, which is used in combination with other oils for scenting soap. The herb itself, when dry and ground, is used in certain sachet powders.

Geranium.—The leaves of the rose geranium—*pelargonium odoratissimum*—are very largely cultivated in Grasse and Cannes for their essential oil, which is obtained by distillation. The plant also grows abundantly in Turkey. The odor of the oil is very agreeable and rose-like, and the color varies from white to brownish, and sometimes greenish. The oil of the *andropogon nardus*, cultivated in the Moluccas, is often used, according to PRESSÉ, for adulterating the oil of rose-geranium. The delightful odor of the true oil of geranium renders it a useful perfume. It is also used extensively for adulterating ottar of rose, than which it is much less costly.

Heliotrope.—The aroma of this plant—*h. peruvianum* and *h. grandiflorum*—resides in the flowers, and is obtained either by infusion or enfleurage. The flowers must be subjected to treatment in their fresh state, and immediately after being gathered. The odor is suggestive of that given by almonds and vanilla combined; and its exquisite fragrance adapts it to the production of the finer kind of compound scents.

Honeysuckle.—This flower, also called woodbine—*caprifolium perfoliatum*—is of luxurious growth, and yields a delicious odor by the process of enfleurage. The poet COWPER thus speaks of it:—

Copious of flower, the woodbine, pale and wan,
But well compensating her sickly looks
With never-cloying odors.

Jasmine.—This plant—*jasmine grandiflora*—is the *yasmyn* of the Arabs. The jessamine flowers in July and August, and is extensively cultivated in the Southern part of France. The essential oil may be obtained by distillation; but as its production is very costly, and the yield very small, resort is generally had to the process of enfleurage for the extraction of the

aroma. This odor is peculiar, but richly fragrant, and enters into the composition of many of the finer scents for the handkerchief. The poet says—

Luxuriant above all,
The jasmine throwing wide her elegant sweets.

Jonquil.—The flowers of this plant—*narcissus jonquilla*—give out an agreeable odor, which may be extracted by the process of enfleurage.

Lavender.—This plant, the common lavender—*lavandula vera*—is one of the most renowned of antiquity, being the spikenard of the ancients. It was then only less employed as a medicament than as a perfume. It is still an ingredient of some few medicinal preparations. Its extensive use in washing and bathing is the origin of its present name, from the Latin word *lavo*, to wash. The plant grows in the Southern parts of Europe, and is largely cultivated at Mitcham in Surrey. The British lavender is the most fragrant, and brings four times the price of that from the continent. By distillation, the flowers yield an essential oil, and also *lavender water*. The sweetness of this perfume and its abundance render it very serviceable.

The French lavender—*l. spica*—also yields a fragrant oil and water by distillation; but they are very far inferior to those from the preceding species. The oil of this latter plant is called the *oil of spike*.

Lemon Grass.—A species of grass, said to be *andropogon schoenanthus*, which grows abundantly in India, and is largely cultivated in Ceylon and the Moluccas. By distillation, the plant yields an essential oil, assimilating in odor to that of the oil of lemon, and sometimes called *oil of verbena*. This perfume is very agreeable and economical, and well adapted for extensive use, either alone or in combination with other scents.

Lilac.—The flowers of this shrub—*syringa vulgaris*—are very fragrant, and yield a perfume by the process of enfleurage, resembling that from the tuberose.

Lily.—The lily of the valley—*lilium candidum*—bears flowers which emit a peculiar and powerful fragrance. This aroma may be extracted by the process of enfleurage; but eight or ten repetitions, with the same fat or bearsoil and fresh leaves, are required to obtain the requisite strength.

Magnolia.—The flowers of this plant—*m. glauca*—are strongly and gratefully odorous. It abounds in the swamps of the Middle and Southern states of South America; and is sometimes called white bay, sweet bay, *et cetera*. The aroma is extracted by the process of infusion or enfleurage.

Marjoram.—A species of thyme—*origanum marjoram*. This herb yields, by distillation, a strong scented essential oil, much used for perfuming soaps. It is called *oil of orangeat* by the French.

Meadow Sweet.—This plant—*spirea ulmaria*—affords a sweet-smelling oil by distillation.

Mignonette.—This plant—*reseda odorata*—is widely cultivated in Grasse and Cannes for its flowers, which are characterized by a peculiar and very delicate fragrance. The odor is extracted by the process of enfleurage; and to give it consistency, the extract is generally mixed with a little violet.

Mint.—The herb—*mentha viridis*—called spearmint, yields, by distillation, a strong-smelling aromatic oil, which is much employed in mouth-washes; and also as an ingredient of compound perfumes for soaps.

Myrtle.—The flowers and leaves of the common myrtle—*myrtus communis*—yield, by distillation, a very fragrant oil. Myrtle-flower water is sold in France by the name of *eau d'auge*.

Neroli.—There are two species of the orange; the Portugal or sweet orange—*citrus aurantium*—and the bitter or Seville orange—*citrus bigaradia*. The flowers of both give very fragrant essential oils and waters by distillation; but those from the latter are the most costly and best esteemed. The oil is called oil of neroli; the water, orange-flower water. The leaves and unripe fruit of the bigaradia also give a volatile oil by distillation, known as essence of petit-grain. The essential oil distilled from the rind of the fruit of the sweet orange, is called essence of Portugal.

All the neroli products are highly esteemed for their delightful odor, and enter largely into the composition of perfumes, particularly that of the savine Cologne water, and other fine bouquets for the handkerchief. The essence of petit-grain is mostly used for scenting toilet soaps; and orange-flower water is very popular as a flavoring material. A few drops of this latter added to ice water, sweetened with white sugar, makes a refreshing summer drink. The odor obtained from the bitter orange flowers, by the process of infusion, is much more natural and delicate than that obtained by distillation.

Patchouly.—This herb—*pogostemon patchouly*—growing extensively in India and China, affords, by distillation, a dark-brown essential oil of very powerful and peculiar odor, which is agreeable when diluted. It enters into the composition of certain bouquet scents. The dry and powdered herb is used for sachet powder, on account of its property of keeping moths out of clothes.

Pea.—The flowers of the sweet pea or chick vetch, *lathyrus odoratus*, as it is also called, eliminate, by a process of infusion, a very grateful odor.

Pink.—The clove pink flower, *dianthus caryophyllus*, gives out a delightful aroma, which may be extracted by the process of enfleurage.

Rose.—This plant, *rosa centifolia provincialis*, is largely cultivated throughout Turkey, at Ghazepore in India, and in the Southern part of France, and also at Mitcham in England, for the manufacture of *rose water*, and *otto* or *attar of rose*. This latter is the essential oil of the flowers; and that made at Grasse takes the precedence of attar from all other countries. The bulk of supplies, however, comes from Turkey and India. The rose water made at Provence is distinguished for its very superior quality. Both it and the attar are obtained by distilling the flowers; two thousand roses yielding little more than a drachm of the latter. The odor may also be extracted by infusion or enfleurage; and thus obtained, it is much more natural and fragrant than that made by distillation. In Asia Minor, the attar is made by distilling the rose buds, without water, by the heat of a saline bath.

The odor is very popular, but must be used in a diluted state.

A fictitious rose water, which, according to WAGNER, might be used in perfumery, is made by decomposing the volatile oil of gaultheria—salicylate of oxide of methyl—with caustic potassa, and distilling. The distillate is the required product, and possesses an odor closely resembling that of the rose. This odor characterizes the products of the spontaneous decomposition of salicylate of potassa.

It has a very general application in the several branches of the art of perfumery.

Rosemary.—This plant—*rosmarinus officinalis*—gives, on distillation, a thin essence, with a characteristic aromatic and stimulant odor. It is generally employed, in combination with other perfumes, as an ingredient of *Hungary water*, *Cologne water*, and certain Bath waters.

Sage.—The leaves of this plant—*salvia officinalis*—are sometimes used, when dried and ground, for scenting soaps; and as an ingredient for sachet powders. The odor is strong, aromatic, and fragrant.

Spike.—This perfume has already been described under the head of *Lavender*.

Syringa.—This plant—*philadelphus coronarius*—is the *mock orange* of America. Its flowers emit an intense odor, very similar to that from orange blossoms; and which may be extracted by the process of infusion or enfleurage.

Thyme.—The lemon thyme—*thymus serpyllum*—yields by distillation an oil of herby, rather than flowery odor; and it is, therefore, rarely used as a perfume. The dried and ground plant is sometimes used in sachet powders. Thyme oil is generally sold as oil of origanum; but the odor of the two is widely different—that of the latter, when genuine, being more like peppermint than thyme.

Tuberose, or *Tubereuse*.—This is a very fleeting perfume, obtained by the process of enfleurage, from the flowers of the *polianthes tuberosa*—largely cultivated for that purpose at Grasse. Its rich and exquisite smell makes it a valuable agent in compounding the finer kinds of bouquets. A little extract of orris or vanilla must be added to impart permanence to it.

Verbena, or *Vervain*.—This is the scented species of the plant, *aloesia citriodora*. By distillation, it affords an odor of rare fragrance, which is seldom to be met with in commerce. The oil of lemon grass, diluted with alcohol, which is closely assimilated to it, is generally vended for it. It is used in *court bouquet*, *Portugal water*, and a number of the finer scents.

Violet.—From the flower of the *viola odorata* is obtained an odor, which, in its genuine state, is of the choicest fragrance. There are few perfumes more highly esteemed. The flowers are largely cultivated at Nice, Grasse, and also in the vicinity of Florence, where they are subjected to the process of infusion, in order to extract their delicious aroma. The essence thus obtained is of a beautiful green color, and has a perfectly natural smell. Tincture of orris root is a base imitation frequently sold for the genuine substance.

Volkameria.—This odor is supposed to be derived from the flowers of the *v. inermis*, which grows in

India. Little is known of it, and PIÈSSÉ gives the following recipe for the composition sold under the name of *essence of volkameria*:—Esprit de violette, and esprit de tubereuse—each one part; esprit de jasmine, four fluid ounces; esprit de rose, eight fluid, and essence of musk, two fluid ounces.

Wall-Flower.—The flowers of this plant—*cheiranthus cheiri*—emit a very delightful aroma, which may be extracted by the process of infusion. It is not much used, and deserves a more general application.

4. FRUITS AND SEEDS.—The materials under this head are not all used for their perfume; indeed, the majority of them serve different, though no less important purposes.

Almond.—This perfume has been much esteemed for many ages. VIRGIL speaks of it in the following lines:—

Mark well the flowering almond in the wood;
If odorous blooms the bearing branches load,
The gibe will answer to the sylvan reign—
Great heats will follow, and large crops of grain.

The kernel of the bitter almond—*amygdalus amara*—gives, on expression, a fixed oil; and the pressed cake which remains, on being macerated in water and distilled, exhales the volatile oil of bitter almonds, which does not exist ready formed in the nut, but is generated by the reaction which takes place between two of its constituents, *emulsin* and *amygdalin*, under the circumstances just mentioned. This golden yellow oil is of a pungent agreeable odor, but is highly poisonous, and must be handled and used with caution, as it always contains more or less hydrocyanic acid. This acid, which averages eight to ten per cent., may be removed by prolonged agitation with a large quantity of milk of lime and caustic potassa, and redistilling. The pure oil is hydride of benzoyl, with some benzoic acid; and it owes its peculiar odor to the former of these components. By judicious use, alone or in combination, it is very serviceable; particularly for scenting pomades, soaps, shaving and cosmetic creams, and meets with general appreciation. The *essence of mirabane*, which is frequently sold as the genuine substance, is an artificial product, known chemically as nitrobenzole. Its odor, however, only approximates to that of the oil of bitter almonds; nevertheless, it is largely employed for scenting soaps. Peach-kernels, by the above process, also afford a volatile oil, which is often palmed off as the genuine oil of bitter almonds. This latter is used for flavoring, as much as for scenting. The kernels or nuts of the sweet almond—*amygdalus dulcis*—do not yield any volatile oil, unless they are mixed with bitter almonds; but they give by expression a very mild fixed oil, which is much esteemed for making cosmetic pastes, creams, and the like. It is called oil of sweet almonds.

Ben.—This plant is the *mohringa optera* and *oleifera*, indigenous to Arabia and Syria, but growing also in the West Indies. By expression a fixed oil results, which is colorless, tasteless, and inodorous. The oil, after repose, separates into two portions; one of which is thick, and the other very fluid, even at low temperatures. The obstinacy with which it retains its neutrality, and resists the rancifying action of prolonged

exposure, combined with other desirable properties, render it an admirable vehicle for the extraction of certain delicate odors. It is, therefore, much in vogue in the process of infusion and enfleurage.

Bergamot.—The rind of the fruit of the *citrus bergamia* gives the well-known oil of bergamot by expression. Its odor is mild and eminently agreeable; and when mixed with other odors, greatly enriches their sweetness. The oil should be kept in tightly-stopped bottles, else its scent will become impaired.

Caraway.—The seeds of this plant—*carum carui*—yield, by distillation, the oil of caraway, much used for perfuming soaps, and particularly that kind known as *old Windsor*. It also enters into the composition of cheap essences. The seeds, in a ground state, are employed in certain sachet powders.

Cedrat.—The rind of the citron fruit—*citrus medica*—yields the oil of cedrat, both by expression and distillation. Its odor is lemon-like. This oil is expensive, and is mixed only with the finer perfumes.

Cloves.—The perfume from this plant, *caryophyllus aromaticus*, is one of the most ancient and useful. Every part of this plant contains aromatic oil, but the flower-buds are the most prolific portion. The oil may be obtained by expression, but much more economically by distillation, which is the mode generally followed. Its odor is strong and fragrant, and renders it a prominent ingredient of a very numerous variety of perfumes.

Cocoa.—The kernels of the cocoa palm, *cocos nucifera* and *butyracea*, growing in Brazil, Ceylon, and Bengal, when ground and subjected to hot-pressure, part with a white butyraceous fat, which has a disagreeable odor, of which it may be relieved by melting it with powdered benzoin, and afterwards straining. It has a limited application for common pomades, and as fat-stock for certain kinds of toilet soap.

Dill.—This plant, *anethum graveolens*, is cultivated in all the countries of Europe, and bears a strong smelling aromatic fruit or seed which, on distillation, eliminates a volatile oil, and a pleasant-smelling water, called *dill water*. This latter, mixed with rose water, is used, according to PIÈSSÉ, as a cosmetic for clearing the complexion. The oil may be employed in combination with others for scenting soaps.

Lemon.—The rind of the lemon fruit, *citrus limonum*, by expression evolves the well-known essential oil of lemons, which comes principally from Messina, and has a delightful odor. By time and exposure it becomes altered, and loses fragrance; it must, therefore, be used fresh. It enters largely into the compound perfumes and Cologne waters, but will not answer for scenting greases, as it promotes their rancidity. Like bergamot oil, it is often adulterated by the dealers with oil of turpentine.

Mace-Nutmeg.—Ground mace is sometimes to be found in sachet powders. It is the reticulated membrane investing the kernel or nutmeg of the *myristicha moschata*. The nutmeg emits by distillation, a fine fragrant volatile oil. It also yields, by expression, a fixed oil, called oil of mace. It is concrete, yellowish, and of an agreeable aromatic odor. Its application in perfumery is very limited.

Orange.—The *essence of Portugal*, heretofore de-

scribed under *Neroli*, is obtained by expression and distillation from the rind of the sweet orange. It is a very agreeable and popular perfume, and the prominent ingredient of many fragrant waters.

Palm.—The palm fruit, *avoira elais*, on being boiled with water, sends to the surface a butyaceous orange-colored fat of a violet-like odor. It is met with chiefly in admixture with tallow to make fine palm soap, and in small quantities for coloring pomades. The odor of the oil may be extracted by infusion in alcohol.

Tonquin.—The tonka or *coumarouma* bean, is the seed of the *dipterix odorata*, a plant growing in Guiana. It emits a strong, agreeable, aromatic odor, which may be extracted by infusion in alcohol. The tincture thus made is used in small quantities in a large number of compound scents, and particularly the *bouquet du champ*, on account of its assimilating in odor to new hay. The bean itself, when ground, forms an ingredient of many sachet powders.

Vanilla.—The pod or bean of the *vanilla planifolia* or *aromatica*, a plant of the West Indies, Mexico, and South America, emits a very fragrant and peculiar odor, which may be extracted in the form of tincture, by infusion in alcohol. It enters largely into the composition of bouquet odors, hair washes, *et cetera*, and is also a favorite material for flavoring confectionary.

5. BALSAMS AND RESINS.—The balsams used in perfumery are, the *Peru balsam*, from the myroxylon peruiferum; *tolu balsam*, from the myroxylon toluiferum; *balm of gilead* or *mecca balsam*, from the amyris opobalsamum; *labdanum*, from the cistus creticus; *storax*, from the liquidamber styraciflua; *benzoin*, from the styrax benzoin; and *myrrh*, from the balsamodendron myrrha. Some are in the form of fluid resins, while others are concrete, as labdanum, myrrh, and benzoin. All are exudations from plants, flowing out naturally, or else produced by incisions. Most of them are of oriental origin, and the supplies of all come from abroad. Their odors are aromatic and agreeable, that of labdanum being amber-like. Myrrh has a peculiar fragrance, and is more used for odontalgic preparations than as a perfume. This class of substances impart their aroma to alcohol in the form of tincture, and in that state are valuable adjuncts to the perfumer. They constitute the *foundation* or less volatile portions of many compound odors, and give consistency to the scent, and fix those ingredients which are more delicate and fleeting. They must be used judiciously, and in small quantities, as directed for the odors of musk, vanilla, and the like. Benzoin is also employed in a powdered state, as an ingredient of certain sachet powders.

The subject of BALSAMS is fully considered in Vol. I., pages 222-35, of this Dictionary. There are two other materials, neither of which belong properly to any of the classes enumerated, and as one of them is of prime importance in the art of the perfumer, they are entitled to an independent paragraph.

ALCOHOL AND CARAMEL.—*Alcohol*.—The manufacture and rectification of alcohol have already been described in Vol. I., pages 48-149. The Editor will only remark, that for the purposes of perfumery it should be wholly free from the odor of fousel oil, which is

peculiar to rye and corn spirit. In that respect, the French grape spirit is peculiarly adapted for the delicate perfumes, as it has rather a grateful aroma itself, which assimilates well with that of the scent substances. The grain spirit, on the contrary, is preferable as a solvent for the strong odors. HYDE proposes to remove fousel oil and analogous matters, by distilling the alcohol—eighty-five to ninety per cent.—with half a per cent. of manganate of potassa or soda, dissolved in a small quantity of water. The valerianic and other acids thus generated from the fousel and associate oils, combine with the alkali of the manganic salt, and remain fixed, while the alcohol passes over, pure and inodorous.

Caramel.—This useful coloring matter is made by heating brown sugar to 400°-430°, dissolving the product in water, and precipitating with alcohol. The blackish brown deposit is pure caramel, readily soluble in water; and it may be separated from the liquid by straining. A commoner article is the heated sugar merely dissolved in water and strained, the subsequent precipitation being omitted.

MINERAL SUBSTANCES.—This class comprises only a few materials, which are used rather as *body* or coloring matters. *Subnitrate of bismuth* is the *pearl white* for the complexion. A less objectionable preparation would be a mixture of *native sulphate of baryta* and *prepared chalk*—precipitated carbonate of lime. These latter two, while being as white as the former, are not, like it, discolored by the sulphur fumes in the atmosphere, nor so particularly injurious to the skin.

Mineral Talc.—A smooth, greenish-white earth, forms the *body* of tinted rouges. The different colored ochres are also sometimes used as pigments for soaps.

EXTRACTION OF SIMPLE ODORS.—*By Distillation*.—This process is necessary for the preparation of nearly all the essential or volatile oils, the fragrant waters, and more particularly Cologne waters. The apparatus consists of a metallic still and its appliances, for general purposes; but in certain cases, such as the distillation of vinegars and other substances that might act upon metal, glass or stoneware retorts are the proper implements. These latter, it should also be remembered, are better applicable for small and nice operations.

Essential Oils.—These so-called oils are misnomers, as they have none of the chemical or physical properties of true oils. They should be more properly designated by the title of *attars*. They differ from the fat or fixed oils in not being saponifiable, or greasy to the touch. They are, moreover, volatile; and being the odorous principle of the plants, each is consequently characterized by a scent. In specific gravity they range from 0.759—attar of coriander—to 1.094—attar of sassafras. They have, generally, an acid burning taste, and while many are colorless, some are yellow, red, or brown, others green, and a few blue. They burn with a brilliant flame and much smoke, and by prolonged exposure become thick and resinified. In ultimate composition they are chiefly hydrocarbons; but some few contain oxygen, and a certain class sulphur as a constituent. Their proximate components are *elaopten* and *stearopten*, the former of which is more fluid than the latter,

and may be separated by pressure when the oil is congealed.

The purity of essential oils is all-important, as they are used solely for their perfume. Those found in commerce do not always have that quality, but are frequently debased with alcohol, spirit of turpentine, resin, balsam copaiva, or some oil of inferior price. The detection of the latter fraud is very difficult—in most cases the specific gravity being the only test. The presence of resin or balsam is elicited when a drop of the suspected oil, heated upon a piece of paper, leaves a greasy spot.

Alcohol is to be tested for, by placing a lump of perfectly dry chloride of calcium in a test-tube containing the suspected oil, and shaking it well. If the attar is pure, the chloride of calcium will remain unaltered; but if it contains alcohol, the lump will dissolve and form a dense substratum.

Spirit of turpentine is often used to cheapen the strong-scented attars, such for example as the attar of lavender. MERO has proposed an excellent method for its detection. It consists in placing one drachm of the attar with an equal volume of oil of poppy in a test-tube, and heating them in a water bath. If the attar does not contain spirit of turpentine, the mixture remains turbid; but if, on the contrary, it be present, the poppy oil is dissolved, and the menstruum becomes clear.

Attar of roses is often mixed with attar of geranium; but the presence of this latter may be ascertained by means of nitric acid, which imparts an apple-green hue to the latter, while it tinges the rose dark yellow.

The still used for the oils should be constructed so as to serve for all the distilling operations of the laboratory, and must, therefore, be set for use either with the naked fire or steam heat, as may be desired. MORFIT, in his *Chemical Manipulations*, describes an excellent arrangement, the whole of which is shown in front view by Fig. 385, just as it appears when in operation. The brickwork in which it is set abuts

Fig. 385.

against the chimney and connects with the flue, through the furnace of the still. This furnace, instead of being in front to inconvenience the operator with its heat and dust, is placed at the side, the lower door being the entrance to the ash-pit, and the upper to the furnace or fire-hole. The refrigerant or cooling-tub, α , has its position to the right of the brickwork.

The lower portion or body of the still, b , is made of heavy sheet-copper tinned interiorly. The head, c , is cast wholly from pure block-tin. Projecting from the inside of the still, near the bottom, is a tinned copper tube d , which passes forward through the brickwork and ends in a stopcock fixture, from which rises a glass tube e . The tap serves to shut off communication between the still and tube, as may be necessary in case of accident to the latter; and the tube itself, graduated into inches, presents a scale which will at all times indicate the height of the liquid. This indicator is protected by a half-casing of metal, in which it rests against the front wall of the brickwork, a clamp or two serving to keep it steady. There are two supplementary parts in the still, one of which is a colandered lining of block-tin, shown by Fig. 386, and the other by Fig. 387, a perforated false bottom of the same material. The first is made to fit to the mouth of the still in such a manner that the same head will adjust with both the inner and outer vessel equally well. The latter is intended as a support for organic or other matters alterable by contact with highly-heated surfaces, and is more particularly adapted for distillations with the naked fire. As it may be necessary frequently to remove this bottom, for the purpose of cleansing it, or dispensing with its use in some operations, it is constructed of two parts, connected by hinges in the centre, so as to form a fold which will pass through the mouth of the still.

Fig. 386.

Fig. 387.

The block tin colander, exhibited in the drawing of the still by dotted lines, is designed for use in the distillation of bulky substances, particularly those of vegetal origin, by a direct current of moist steam. It allows, in a degree, the application of the displacement principle in distillation; for, as the current of steam enters, it passes upwards through the holes, thence through the mass of matter supported in the colander, and the first portion of the distillate reaches the condenser saturated with the volatile parts of the substance under treatment, and without mixture of any light, solid particles driven over mechanically, as would otherwise be the case. The process effects filtration at the same time that it constantly renews the surface of the solid matter to the solvent action of succeeding relays of fresh steam, while it also affords the means of determining when the former is exhausted, and the distillation should be stopped.

The steam-pipe is introduced through the opening, o —Fig. 385—and leads to within an inch of the bottom, where it takes an angular bend, and ends in a rose, which is a perforated copper ball, with a screw-cut shoulder, by which it is attached to the steam-pipe. The latter is so adjusted in the opening, by means of a shoulder and coupling-nut, as to form a tight joint. When the still is to be used with the naked fire *alone*, this pipe must be removed, and the opening closed with a screw-plug provided for the purpose. It should be remarked that this opening serves also for the entrance of a funnel—

tube through which to introduce fresh additions of liquid as may be required, to maintain a supply in the still, without the necessity of stopping the operation or removing the head.

The distillate, in passing from the still-head, goes into a worm, *g g*, firmly fixed in the cooler, *a*. The worm is a series of block-tin tubes, as shown by the dotted lines. The mouth of the first joint receives the beak of the still-head, and that of the last joint empties, through a bent nozzle, into the receiving-vessel, generally a glass or stone jar, as seen at *d*. To facilitate the cleansing of the joints, they are fitted at the ends, *g*, with screw-plugs, which being removed, allow free access to the interior with a cloth and ramrod.

The cooler is made of galvanized iron, or, still better, of tinned copper; and in order to accommodate the long joints of the worm which is soldered to it, its form is oval. The pipe through which it receives cold water is close to the side, and extends nearly to the bottom, as shown at *s*. A connection with the hydrant is made by a branch-pipe and tap, as shown at *m*. The opening for the exit of the warm water is seen at *f*, and leads into another pipe, *h*, running down the outside of the cooler into the drain or gutter. A tap, *x*, serves for draining off sediment, as it accumulates by deposition from the water.

When it may be desired to use dry steam, then the block tin colander, Fig. 386, must be replaced by one which is close and not perforated. There will then have to be an opening and tube opposite to *o*, for carrying away excessive steam.

Fig. 388.

The jacket thus formed gives the convenience of using it also as a water or saline bath, when operating with fire direct, instead of steam. The water or saline solution is, of course, placed in the outer case or body of the still proper, *b*, and thus surrounds the inner vessel, containing the matter to be distilled. Steam may be supplied from a small portable generator, such as are now made for purposes of this kind, and here shown by Fig. 388. Great care is requisite in cleaning the several parts of the still arrangement at every change of operation.

In the distillation of roots, woods, barks, flowers, seeds, *et cetera*, the best heating medium is steam, as it allows a better regulation of tem-

perature than can be accomplished in the use of the naked fire. Moreover, it removes all liability of scorching the materials. A current of steam passing from the generator under a pressure of fifty pounds to the square inch, has a temperature of 280°, which

is much higher than is needed for any material under present consideration.

The part of the plant yielding the odor, after having been bruised or cut into small pieces, is to be placed in the colandered vessel, or on the perforated bottom, with as much water only as is necessary to drench the material; and when the oil to be obtained is heavier than water, the density of the latter must be increased by nearly saturating it with table salt, which also raises its boiling point from 212° to 220°. The head of the still—Fig. 385—is then put in place, and the joints closed. Steam is next let on through the pipe, *o*, and the current continued until oily distillate ceases to come over.

If the quantity of water is too much in proportion to the amount of material to be distilled, then a portion of the oil remains dissolved therein, and does not separate. The same result occurs when the oily constituent is in limited quantity. In all such cases cohobation is necessary. That is, the distillate or liquor first passing over must be poured back repeatedly, upon the same or fresh material, and as

often redistilled. Indeed, in all distillations where fresh relays of water are used, the last running, which is of feeble strength, should be reserved as the first water for the next operation with fresh material. In this way the small portion of oil which it may have contained is economized. As the volatilization of the water is coincident with that of the oil, the two must be received together, as they condense, in a vessel which will admit of the ready separation of them by reason of their different specific gravities. Fig. 389 represents the Florentine receiver, which is used for the lighter oils. The oil, accumulating at *a b*, retains its supernatant position throughout the distillation, while the water beneath flows out at *c*, as fast as it runs from the still. When the oil is denser than the water, a different arrangement, as shown at Fig. 390, is required. The denser oil is drawn off, by opening the tap of the barrel, as fast as it separates and subsides from the lighter water.

It is very necessary that the water in the refrigerant should be replaced by cold water as fast as it becomes warm; except for those oils, such as anise and rose, which thicken readily. The temperature of the water must be regulated in accordance with that property.

Fig. 389.

Fig. 390.

Scented Waters.—All substances which yield essential oils, give at the same time a scented water of superior excellence; for example, *orange flower water*; and the difference in the density of the two products permits their separation in the manner just described. There are some materials, again, which are too feeble in odor to give an attar, and may yet be made to impart their scent to water. In either of those cases, and also when it may be desired to obtain only a water from those substances which would yield an essential oil, the quantity of water employed must be much larger than for the oil distillations. And for the reason, that now the object is to obtain solution of *all* the essential oil in water, and not to promote the separation of the two, as before directed.

The process and manipulations are the same as just described for distilling the essential oils, except that only the first three-fourths of the distillate are preserved. A little rectified spirit may be advantageously added, before setting aside the scented water for preservation. Wet steam is by far the preferable means of heating. The flowers should be as fresh as possible, and free from stems. *Double distilled rose water* is made by distilling over two gallons from a mixture of twelve pounds rose leaves, and two and a half gallons water. In the same way, nine pounds of elder flowers and four gallons of water give three gallons of *elder flower water*.

By Expression.—This method is adapted only for those substances which are very rich in essential oil; as examples, the rinds of the lemon, orange, citron, and some other fruits. The chief implement is a powerful press. The material is either inclosed in hair bags, or a tinned metal box—Fig. 391—

Fig. 391.

Fig. 392.

Fig. 393.

resting upon the bottom of the press. The box must be lined with a perforated cylinder—Fig. 392—having perpendicular ribs on the exterior circumference. These latter, projecting against the inner sides of the box, form channels by which the flow of the expressed oil is facilitated, and its free passage into the receiving vessel maintained. Being in two parts, connected by a hinge and movable pin, it can be conveniently emptied and refilled, as becomes necessary. The follower—Fig. 393—being directed forcibly downwards upon the contents of the box by the mechanism of the press, crushes

the oil vesicles, and drives out the oil, and along with it some water and mucilage, and foreign matters, which may be separated by sufficient repose and straining.

By Infusion or Maceration.—This process is mostly used for those substances, the odor of which is too delicate for distillation, such as the flowers of the cassie, bitter orange, and violet; and sometimes also the rose and the like, the natural perfumes of which it is desired to obtain in the maximum state of perfection.

The infusion medium is a mixture of beef or mutton

suet, and lard, refined in the manner already directed. The necessary apparatus is one of the steam pans heretofore referred to, but it must be tinned or enamelled interiorly, and fitted with a tight cover. The fat body having been melted, the flowers or odoriferous material are wholly immersed in it, and left for a day, care being taken to stir the mixture occasionally with a wooden stick. In this time the flowers have become exhausted of their perfume by the fat, and must, therefore, be separated by remelting, straining through a fine hair-cloth sieve, and pressing the marc. The spent flowers are then replaced by a fresh charge; and so these renewals are continued until the fat has sufficient odor. In this way various strengths may be obtained, and are generally designated by numbers, according to the number of infusions which the fat has undergone. After the last straining and pressing, the expressed matter should be allowed sufficient repose to clean itself. The darker substratum which thus deposits may then be removed from the clear upper portion, and sold as an inferior quality.

In this manner the finer sorts of French pomade are prepared. Sometimes oil of ben takes the place of suet as the infusion medium, and then the products have the name of *huile antique*.

By Enfleurage.—There are certain flowers, the odors of which are so delicate that they will not bear even the little heat used in the preceding method; and for these the process of enfleurage or absorption is employed. Jessamine, mignonette, tuberose, and similar flowers, belong to this category.

HANBURY thus describes the operation as conducted at Grasse and Cannes. The apparatus required is merely a number of shallow wooden frames of about eighteen by fifteen inches, inclosing at half their depth a sheet of glass. The edges of the frame rise about an inch above each surface of the glass, and, being flat, the frames stand securely upon one another, forming often considerable stacks. The technical name for the frames is *chassis*; those just described are called *chassis aux vitres*, or *chassis aux pommades*, to distinguish them from a different form, which is used where oil has to be submitted to the process of enfleurage. The process in the case of pomade is thus conducted: the unscented fat is weighed into portions, each sufficient for one side of the sheet of glass of a *chassis*. It is then spread over the glass with a spatula in a layer hardly a tenth of an inch thick, care being taken, by employing a little inner frame during the spreading, that the fat does not come in contact with the wood-work of the *chassis*. One surface of the glass having been thus coated, the other is covered in like manner, and the *chassis* is ready to receive the flowers. These are now thinly sprinkled, or rather laid, one by one, upon the surface of the fat, where they are allowed to remain until the next day or day after, when they are dexterously removed with nippers, so as not to soil the fat, and fresh flowers supplied. The *chassis*, charged with fat and flowers, are stacked one upon the other, forming, in fact, a number of little rectangular chambers, the upper and lower surfaces of each of which are of glass, covered with a thin layer of fat sprinkled with flowers, the sides being of wood. In one manufactory

which the Editor inspected, only one surface of each *chassis* was coated with fat, the jessamine flowers being placed in an abundant layer upon the other surface. In another establishment the flowers of mignonette were being similarly treated. In this arrangement the flowers do not, of course, come in contact with the fat, but the latter is simply suspended above them to receive and absorb their odor. The flowers require changing, either daily, or every other day, for a month or two, before the pomade is sufficiently impregnated with their odor. It is of paramount importance that all flowers employed in this process should be collected during warm weather.

After the last impregnation, and when the fat is sufficiently fragrant, the pomade is removed with a spatula, and put into close cans.

By Alcoholic Solution.—The extraction of odors by means of alcohol from scented fats, will be more fully explained under the head of *Extraits*. The Editor will here limit himself to the description of essences and tinctures.

ESSENCES.—These, in the language of perfumery, are nothing more than solutions of essential oils in deodorized alcohol. The proportion of oil varies from two drachms to two ounces, and the manipulation consists in merely mixing and shaking the two together. Sometimes they are subsequently distilled with a little water, and then they are called *distilled aromatic spirits*. Cologne, lavender, and similar waters are thus made. For example, SMYTH makes his famous *essence of lavender* by mixing together—English attar of lavender, four ounces; deodorized alcohol of ninety-five per cent., five pints; rose water, a pint; and distilling off, five pints.

As examples of essences by simple mixture may be named—

	Essential Oil.	Deodorized Alcohol of 95 per cent.
Essence of lemon,.....	one fluid ounce.	a quart.
“ bergamot,.....	—	a quart.
“ rose—triple,...	one ounce and a half.	two quarts.
“ thyme,.....	two drachms.	two quarts.

Tinctures.—When both of the substances are fluid, as in the case of certain balsams, then the spiritous solution is made by merely mixing the two together as before, in suitable proportions. For instance—

	Tolu balsam.	Alcohol.
Tincture or essence of tolu,....	three drachms.	a quart.

There are, however, many solid substances which are treated with alcohol, for the extraction of either their odor or coloring matter. These menstrua may

be made by merely macerating the substance in alcohol for ten days, and filtering off the clear tincture; but the shorter and more efficient, as well as economical method, is that known as *displacement*. To explain the operation intelligibly, let one suppose that benzoin is under treatment. The apparatus, made wholly of glass, having been arranged as shown by Fig. 394, and a plug of raw cotton dropped loosely at *b*, the benzoin in coarse powder is then poured into the tube portion, *A*, until it reaches the line *c*. Alcohol, of 66° Twaddell, is next added, until it rises to the line *d*. As soon as the first portion sinks into the benzoin, a fresh addition must be made; and thus the succeeding relays go on displacing those which preceded them, without mingling with them. Each stratum becomes more and more charged with soluble matter as it descends; and when it reaches the bottom of the mass, under the pressure of the superincumbent liquor, it runs out saturated. When, by successive additions of fresh alcohol, the benzoin has become exhausted, the liquid passes through the mass, and falls into the receiver, *B*, as tasteless and colorless as when first poured in. This indicates the completion of the process. As atmospheric pressure is an important element in the operation, it will not answer to shut it off by closing the top of the displacer, without making some compensating arrangement; and, therefore, a communication between the upper and lower vessels is established by means of a latent-tube arrangement, *D*. In this manner the apparatus is kept close, and the evaporation of alcohol prevented, while the pressure produced is distributed throughout the vessel, and thus rendered uniform. As the runnings are clear, filtration is rarely necessary. The quantity of alcohol thus consumed need not be more than sufficient to exhaust the material; and the resulting tincture must therefore be diluted to the proper strength. Deodorised alcohol must be always used.

The following are the proportions employed for the most important tinctures or essences:—

		Troy.	Alcohol.
Tincture or essence of vanilla,.....	vanilla bean—rasped,.....	eight ounces,.....	eight pints.
“ “ musk,.....	grain musk,.....	two drachms,.....	eight pints.
“ “ frangipani,.....	powder a la frangipani,.....	one pound,.....	six pints.
“ “ rhodium,.....	rhodium wood—rasped,.....	one pound,.....	two quarts.
“ “ civet,.....	civet, orris root,.....	half an ounce,.....	two quarts.
“ “ tonquin,.....	tonka bean,.....	one pound,.....	eight pints.
“ “ orris,.....	orris root,.....	seven pints,.....	eight pints.
“ “ alkanet—red color,...	alkanet,.....	half an ounce,.....	a quart.
“ “ turmeric—yellow,...	turmeric,.....	half an ounce,.....	a quart.

POMADES.—The *fine*, and *extra fine* or *double* pomades are made by the processes of maceration and enfleurage, which have been already described at page 671. The

body must be of fat purified as previously directed. Almond paste, peeled and bruised almonds, may also be scented in the same manner here directed for fats.

Fig. 394.

Pomade à l'Acacia.—Cassie leaves, fifteen pounds; body, fifty pounds, consisting of thirty-five pounds lard body, and fifteen pounds of mixed beef and mutton suets. The infusion must be repeated ten times, and each time with a fresh quantity of fifteen pounds of flowers.

Pomade à la Rose.—One pound of body and twelve infusions, and each time with one pound of fresh rose leaves.

Pomade à la Fleur d'Oranger.—Equal parts of flowers and body. Eight infusions give the required strength.

Pomade à la Vanille.—One pound of vanilla in shreds, and twelve pounds body. Infuse for twelve days; remelt, and infuse for ten days longer; melt again, and strain through a fine sieve.

Pomade à la Tubéreuse.—The enfleurage must be repeated with fresh tuberoses flowers, six or more consecutive times.

Pomade aux Jasmin.—The jessamine flowers must be renewed ten times.

Pomade à la Jonquille.—The jonquil flowers need only five or six renewals.

Pomade à la Jacinthe.—The hyacinth flowers require to be renewed eight or ten times for a highly-scented pomade.

COMPOUND OR BOUQUET POMADES.—These are made by a judicious mixture of the single pomades, of which the preceding are some examples.

Pomade aux Fleurs d'Italie.—Pomades à l'acacia, à la tubéreuse, à la jacinthe, à la jonquille, each one pound. Pomades à la fleur d'oranger and au jasmin, each two pounds. Pomades au reseda and à la rose, each eight ounces. Melt together over a water-bath, color as may be desired, and strengthen the perfume with a mixture of tincture of musk, six drachms; tincture of amber, three drachms; essence of bergamot, three drachms; and essence of cloves, one ounce.

Pomade à la Frangipani.—Plain body, and pomade aux jasmin, each four pounds. Pomades à la fleur d'oranger, two pounds. Pomades à l'acacia and à la rose, each one pound. Melt together over a water-bath, and as the mass begins to cool, stir in a mixture of tincture of vanilla, four ounces; balsam of peru, one ounce; essence of bergamot, two ounces; essence of cloves, half an ounce; and tinctures of amber and musk, each four ounces. Color brown.

The name FRANGIPANI belongs to a very ancient and illustrious Roman family, and certain popular preparations are so called in honor of the grandson of MUTIO FRANGIPANI, one of its scions, who originated many agreeable combinations of perfumes during the time of LOUIS XIII. of France.

The perfume called after the above, as found in commerce, is a compounded scent, and not, as supposed, a simple extract of the *plumeria alba*, a fragrant plant of Antigua, originally named the FRANGIPANI shrub, after its discoverer.

Pomade Impériale.—Pomades à l'acacia, à la jonquille, au lilas, au réséda, à la tubéreuse, each eight ounces; pomade au jasmin, four pounds; pomade à la fleur d'oranger, one pound. Melt together over a water bath, taking care to add the pomade au lilas and

pomade au jasmin last. When nearly cool, stir in a mixture of essence of bergamot, and tincture of vanilla, each one ounce; tinctures of musk, amber, and fenugree, each two drachms; color green.

The common grade of pomades are composed of the unscented body used for preparing fine pomades, which is extemporaneously perfumed by merely stirring in the essential oils, singly or in *bouquet*, according to the odor it is desired to impart. Beef marrow, or bears' grease, are scented in this manner. White wax is to be added for *stick pomatum*.

Pomade à la Graisse d'Ours.—Bears' grease, purified, six pounds; pomade à la rose, one pound; melted together, and perfumed with essence of rose, one ounce; tincture of vanilla, one ounce.

Pomade de Moelle Bœuf.—Purified beef marrow, eight pounds. Melt, and perfume with tinctures of musk and benzoin, each two drachms; essence of portugal, one ounce; essential oil of lavender, two ounces; extract of jasmin, one ounce; and attar of roses, half an ounce. Color with a portion of unscented body, in which fresh walnut leaves have been infused.

ANTIQUÉ OILS.—These oils are prepared as already directed for the process of maceration and enfleurage; and they correspond with the pomades, except that olive or ben oil is used for the body instead of solid fat.

Huile Antique de la Rose de Provens.—Oil and rose leaves, each one pound. Infuse seven times, with as many relays of fresh flowers.

Huile Antique au Chevre-feuille.—Honeysuckle flowers and oil. Infuse eight to ten times, with as many relays of fresh flowers.

COMPOUND OILS.—These are judicious mixtures of the single oils. One example will suffice.

Huile Antique de Millefleurs; ou, de Bouquet Composée.—Oils au jasmin, à la rose, each eight ounces; oils à l'acacia, à la fleur d'oranger, à la tubéreuse, each four ounces; oils à la jonquille, à la jacinthe, à la vanille, each two ounces. Mix together.

The inferior qualities of the above oils are made from olive oil alone, or mixed with lard oil, scented, extemporaneously, with essential oils; for example:—

Huile à la Bergamot.—Essence of bergamot, two ounces; added to one pound of olive oil.

Huile de Neroli.—Essential oil of neroli, four ounces; and olive oil, one pound.

SINGLE EXTRACTS OR EXTRAITS.—These preparations are made by treating with alcohol the highly-scented pomades, or antique oils, obtained by the processes of maceration or enfleurage. In this way the aroma absorbed from the flowers by the fat is dissolved out. These spiritous infusions are of much more delicate odor than the so-called *essences* or *solutions* of volatile oil in alcohol. Indeed, they represent in themselves the primitive odor, in liquid form, of those plants which do not yield any volatile oil.

The scented pomade is placed in a stone vessel, and one pint of deodorized spirit added to every pound of pomade. The whole is then heated for three days over a water bath, and frequently stirred in the interval; after which the alcoholic liquor is drawn off from the fat, and put through the same operation repeatedly, with fresh quantities of pomade, until it has acquired sufficient

strength of odor. A revolving churn may be substituted for the digesters and water bath; and this arrangement has the advantage of eliminating the perfume in a state of great integrity, there being no heat used. The churn may be barrel-form, and placed horizontally, so as to facilitate the turning of the crank which imparts motion to the dash-paddle in the interior.

The liquors thus obtained are simple extracts of the most superior quality and natural odor, and form the bases of the compound extracts or *bouquets* so popular as perfumes for the handkerchief.

The pomade or oil, after treatment, still retains some odor, and is, therefore, valuable material for the stick and common pomades, or as fat stock for new treatment with fresh flowers.

Extrait de jasmin, Extrait de violette, Extrait de tubéreuse, are examples of preparations made according to the preceding directions.

COMPOUND EXTRACTS OR BOUQUETS.—*Extrait de bouquet.*—Extraits de jasmin et violette, each two pints; extraits d'acacia, rose, œillet, et des fleurs d'oranger, each one pint; flowers of benzoin, two drachms; tincture of amber, four ounces. Mix and filter.

Bouquet d'Amour.—Extraits de rose, jasmin, violette, acacia, each one pint; tinctures of musk and ambergris, each half a pint. Mix and filter.

Jockey-club Bouquet.—Extraits de rose et tubéreuse, each one pint; extrait de cassie, half a pint; extrait de jasmin, four ounces; tincture of civet, three ounces. Mix and filter.

Bouquet des Millefleurs.—Extrait de rose, one pint; extraits des tubéreuse, jasmin, fleur d'oranger, cassie, et violette, each half a pint; essence of cedar, four ounces; tincture of vanilla, ambergris, and musk, each two ounces; essence of rose, half a pint; attar of bergamot, one ounce; attars of almonds, neroli, and cloves, each ten drops. Mix, leave to repose for a week, and filter.

Bouquet de la Reine.—Extraits de rose et violette, each one pint; extrait de tubéreuse, half a pint; extrait de fleur d'oranger, four ounces; attar of bergamot, two drachms. Mix and filter after a week's repose.

Bouquet Royal.—Extrait de rose, one pint; extraits des jasmin et violette, each eight ounces; extraits d'acacia et verveine, each two and a half ounces; essence of rose, half a pint; attars of lemons and bergamot, each two drachms; tinctures of musk and ambergris, each one ounce. Mix, and after eight or ten days' repose, filter.
